rigidity, and mucosal destruction. Several studies have found that almost all gastric ulcers with an unequivocally benign appearance on double-contrast examinations are benign lesions.^{69,99} In those studies, about two thirds of all benign ulcers had a benign radiographic appearance, so unnecessary endoscopy can be avoided in most patients with gastric ulcers diagnosed on double-contrast examinations. This finding has important implications for the evaluation of gastric ulcers because barium studies are safer and less expensive than endoscopy.

Unequivocally benign gastric ulcers are characterized en face by a round or ovoid ulcer crater surrounded by a smooth mound of edema or regular, symmetric folds that radiate directly to the edge of the crater (see Figs. 29-9, 29-13A, 29-14A, and 29-16A).^{69,99} The areae gastricae adjacent to the ulcer may be enlarged as a result of inflammation and edema of the surrounding mucosa (see Fig. 29-6A).⁶⁹ When viewed in profile, benign gastric ulcers project outside the gastric lumen and are sometimes associated with a smooth, symmetric ulcer mound or collar or with smooth, straight folds that radiate to the edge of the ulcer crater (see Figs. 29-4, 29-6, and 29-15A).

In contrast, malignant ulcers are characterized en face by an irregular ulcer crater eccentrically located within a discrete tumor mass.⁶⁹ There may be focal nodularity of the surrounding mucosa or distortion or obliteration of adjacent areae gastricae because of tumor infiltrating this region.⁶⁹ Although radiating folds may be present, they are often nodular, clubbed, fused, or amputated because of infiltration of the folds by tumor (Fig. 29-20).¹⁰⁰ When viewed in profile,

malignant ulcers do not project beyond the expected gastric contour, and there is often a discrete tumor mass that forms acute angles with the adjacent gastric wall rather than the obtuse, gently sloping angles expected for a benign mound of edema (Fig. 29-21).

Equivocal ulcers are those that have mixed features of benign and malignant disease, so a confident diagnosis cannot be made on radiologic criteria. For example, edema and inflammation surrounding a benign ulcer may result in enlarged, distorted areae gastricae, mass effect, or thickened, irregular folds, producing an indeterminate radiographic appearance (Fig. 29-22). Similarly, NSAID-induced greater curvature ulcers that have an apparent intraluminal location or substantial associated mass effect and shouldered edges may result in equivocal radiographic findings (see Fig. 29-8A). Most ulcers that have an equivocal appearance are ultimately found to be benign lesions. Nevertheless, it seems prudent to err on the side of caution by suggesting the possibility of malignant tumor for some benign lesions to avoid missing an early cancer.

Gastric ulcers that have an unequivocally benign appearance on double-contrast studies can be followed with serial double-contrast studies until complete healing without need for endoscopic evaluation.⁶⁹ However, ulcers that have an equivocal or suspicious appearance should be evaluated by endoscopy for a more definitive diagnosis. Although endoscopy is a sensitive technique for diagnosing gastric carcinoma, false-negative biopsy specimens and brushings have been reported in some patients with malignant lesions.¹⁰¹ If the radiographic findings are suggestive of malignant tumor, negative histologic or

Figure 29-20 Malignant gastric ulcer. This patient has an irregular ulcer on the posterior wall of the antrum with scalloped borders and nodular, clubbed folds surrounding the ulcer. These are classic features of a malignant gastric ulcer. (From Levine MS, Creteur V, Kressel HY, et al: *Benign gastric ulcers: Diagnosis and follow-up with double contrast radiography*. Radiology 164:9–13, 1987.)

Figure 29-22 Benign gastric ulcer with an indeterminate radiographic appearance. A small ulcer (arrow) is seen near the lesser curvature with enlarged, nodular areae gastricae surrounding the ulcer because of edema and inflammation of the adjacent mucosa. Although the radiographic findings are equivocal, endoscopic biopsy specimens revealed no evidence of tumor, and a follow-up study after treatment showed complete healing of the ulcer.

Figure 29-21 Malignant gastric ulcer. This patient has an ulcerated mass on the greater curvature of the antrum. Note how the ulcer (black arrows) projects inside the gastric lumen within a discrete tumor mass etched in white (white arrows) that forms acute angles with the adjacent gastric wall rather than the obtuse angles expected for a benign mound of edema. These are classic features of a malignant gastric ulcer.

cytologic findings therefore should not be taken as definitive evidence of a benign ulcer. Instead, follow-up barium studies should be performed until complete ulcer healing is documented. If the ulcer fails to heal with adequate medical treatment, or if it continues to have a suspicious radiographic appearance, repeat endoscopy and biopsy may be required. Even if endoscopic biopsy specimens and brushings remain negative, surgical resection should be considered for some patients with suspicious findings or intractable ulcers on serial barium studies.

DUODENAL ULCERS

In contrast to gastric ulcers, duodenal ulcers are almost always benign. When duodenal ulcers are detected on barium studies, these patients can therefore be treated medically without need for endoscopy. Unlike gastric ulcers, duodenal ulcers are often located on the anterior wall of the duodenal bulb, so prone compression views of the duodenum should be obtained routinely to detect these lesions. Duodenal ulcers may also be obscured by edema, spasm, or scarring of the bulb. Conversely, barium trapped in the crevices of a deformed bulb can mimic ulcer craters. Radiologists should therefore be aware of the limitations of barium studies in diagnosing duodenal ulcers and of the need to perform a biphasic examination in these patients.

Examination Technique

Double-contrast views of the duodenum must be complemented by prone compression views to demonstrate ulcers on the anterior wall of the bulb.¹⁰² These anterior wall ulcers may be hidden in the barium pool unless adequate compression of the bulb is obtained with an inflatable balloon or other prone compression device (Fig. 29-23). Other duodenal ulcers are best seen on upright compression views. Thus, optimal radiologic

Figure 29-23 Importance of prone compression for anterior wall duodenal ulcers. **A.** Initial prone view shows no evidence of a duodenal ulcer. **B.** Prone compression of the bulb with an inflatable balloon clearly demonstrates an ulcer crater (arrow) on the anterior wall. This ulcer was hidden in the barium pool on the earlier radiograph.

evaluation of the duodenum requires a biphasic examination that includes double-contrast views of the duodenal bulb with a high-density barium suspension and prone or upright compression views with a low-density barium suspension.¹⁰³

Shape

Most duodenal ulcers appear as round or ovoid collections of barium (Fig. 29-24). About 5% of duodenal ulcers diagnosed on double-contrast studies have a linear configuration (Fig. 29-25).^{68,104} These linear ulcers tend to be located near the base of the duodenal bulb and often have a transverse orientation in relation to the bulb (see Fig. 29-25A).¹⁰⁴ As in the stomach, linear ulcers are thought to represent a stage of ulcer healing,^{66,104} and they may be indistinguishable from linear ulcer scars.

Size

Most duodenal ulcers diagnosed on double-contrast studies are smaller than 1 cm. A major advantage of double-contrast technique is its ability to demonstrate small ulcers, frequently no more than several millimeters in diameter (see Fig. 29-24B and C). Nevertheless, giant ulcers are occasionally detected in the duodenum (see later, “Giant Duodenal Ulcers”).

Location

About 90% of duodenal ulcers are located in the duodenal bulb and the remaining 10% in the postbulbar duodenum.^{46,105} Bulbar ulcers may involve the apex, central portion, or base of the bulb (see Fig. 29-24). Unlike gastric ulcers, which rarely develop on the anterior wall, as many as 50% of duodenal ulcers are located on the anterior wall of the bulb.^{77,106} Postbulbar ulcers are usually located in the proximal descending duodenum above the papilla of Vater (see later, “Postbulbar Ulcers”). Thus, the presence of one or more ulcers distal to the papilla should raise the possibility of Zollinger-Ellison syndrome (see later, “Zollinger-Ellison Syndrome”).

Morphologic Features

Bulbar Ulcers. Ulcers in the duodenal bulb usually appear as discrete niches that can be visualized en face or in profile (see Fig. 29-24). The ulcers are often surrounded by a smooth, radiolucent mound of edematous mucosa. Occasionally, the size of the ulcer mound may be quite striking in relation to the central crater (see Fig. 29-26B). Bulbar ulcers also tend to be associated with radiating folds that converge centrally at the edge of the crater (see Fig. 29-24B and C). In patients with shallow ulcers or small healing ulcers, the ulcer crater may be visible only with optimal radiographic technique. Thus, the presence of radiating folds should prompt a careful search for an active ulcer at the site of fold convergence before attributing these folds to an ulcer scar.

As in the stomach, ulcers on the anterior wall of the duodenal bulb may be difficult to detect on routine double-contrast views. Other anterior wall ulcers may be manifested by a ring shadow caused by barium coating the rim of the unfilled ulcer crater (Fig. 29-26A).⁸⁵ These anterior wall ulcers can be demonstrated by obtaining prone or upright compression views of the bulb to fill the crater with barium (Fig. 29-26B).

Duodenal ulcers are often associated with considerable deformity of the bulb secondary to edema and spasm accompanying the ulcer or scarring from a previous ulcer (see Fig. 29-24B).¹⁰² This deformity may obscure small ulcers in the bulb, resulting in a substantial number of false-negative examinations. It is therefore important to recognize the limitations of the radiologic diagnosis of duodenal ulcers in the presence of a deformed bulb. Nevertheless, symptomatic patients with a deformed bulb on barium studies should probably be treated for an active duodenal ulcer because of the high risk of ulcer disease, whether or not an ulcer is demonstrated with certainty.

Postbulbar Ulcers. Postbulbar ulcers are usually located on the medial wall of the proximal descending duodenum above the

Figure 29-24 Duodenal ulcers in various locations. **A.** A large ulcer (arrow) is seen at the apex of the bulb. **B.** A small ulcer (arrow) is present in the central portion of the bulb. This ulcer is associated with radiating folds and bulbar deformity. **C.** A small ulcer (arrow) is seen at the base of the bulb, with folds radiating toward the ulcer crater. (**A** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

The ulcer has a transverse orientation in relation to the bulb. **B.** In another patient, a linear ulcer (arrows) is seen at the apex of the bulb. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 29-26 Ring shadow caused by an anterior wall duodenal ulcer. **A.** Supine oblique double-contrast view of the duodenum shows a ring shadow (arrow) in the bulb as a result of barium coating the rim of an unfilled ulcer crater on the nondependent surface. **B.** Prone compression view shows filling of the anterior wall ulcer (arrow). Note the large radiolucent mound of edema surrounding the ulcer. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 29-27 Postbulbar duodenal ulcers. **A.** An ulcer (arrow) is seen on the medial wall of the proximal descending duodenum. There is also a smooth, rounded indentation of the lateral wall caused by associated edema and spasm. **B.** Another patient has a large, relatively flat ulcer (arrow) on the medial wall of the postbulbar duodenum above the papilla of Vater. Folds radiate toward the ulcer crater.

papilla of Vater (Fig. 29-27).^{46,105,107} These ulcers are notoriously difficult to demonstrate on barium studies, presumably because severe edema and spasm accompanying the ulcer prevent visualization of the ulcer crater. This edema and spasm often result in circumferential narrowing of the adjacent lumen or eccentric narrowing with a smooth, rounded indentation on the lateral wall of the descending duodenum opposite the crater (see Fig.

29-27A).¹⁰⁷ If the ulcer crater itself is obscured by edema and spasm, this indentation may be the only radiologic sign of a postbulbar ulcer (Fig. 29-28).

Many postbulbar duodenal ulcers are larger than 1 cm, so they tend to be larger than bulbar ulcers, which are usually smaller than 1 cm.⁴⁶ Large postbulbar ulcers may cause marked narrowing of the adjacent duodenum proximally and distally,

Figure 29-28 Postbulbar duodenal ulcer not visualized on barium study. A prominent indentation is seen on the lateral aspect of the proximal descending duodenum (arrow) as a result of edema and spasm accompanying a postbulbar ulcer that was not visualized on this study. The ulcer was seen at subsequent endoscopy.

secondary to severe edema and spasm accompanying these ulcer craters (Fig. 29-29).⁴⁶ The larger size of the ulcers could help explain the higher prevalence of upper GI bleeding and the poorer response of postbulbar ulcers to medical therapy.⁴⁶ Healed postbulbar ulcers may occasionally be associated with focal scarring and fibrosis, resulting in the development of a so-called *ring stricture* with eccentric narrowing of the postbulbar duodenum (Fig. 29-30).¹⁰⁸ An annular pancreas constricting the postbulbar duodenum may produce similar findings.

Giant Duodenal Ulcers. Giant duodenal ulcers are defined as duodenal ulcers larger than 2 cm.¹⁰⁹ These ulcers are important because of a greater risk of complications such as perforation, obstruction, and upper GI bleeding.¹¹⁰ Nevertheless, treatment with antisecretory agents may lead to dramatic ulcer healing, so these patients can often be managed conservatively without need for surgery.¹¹¹ Giant duodenal ulcers are almost always located in the duodenal bulb and may be so large that they replace virtually the entire bulb (Figs. 29-31 and 29-32). Paradoxically, giant ulcers can be mistaken on barium studies for a scarred or even normal bulb. However, the duodenal bulb would be expected to change in size and shape at fluoroscopy, whereas these giant ulcers will have a fixed, unchanging configuration (see Fig. 29-32).^{109,111,112}

Giant duodenal ulcers may occasionally be recognized on ultrasound studies as discrete, hypoechoic cystic lesions anterolateral to the head of the pancreas.¹¹³ The differential diagnosis

for these lesions includes a duodenal diverticulum and pancreatic pseudocyst. In such cases, a barium study should be performed for a more definitive diagnosis.

Multiplicity

About 15% of patients with duodenal ulcers have multiple ulcers.¹¹⁴ Most of these are located in the duodenal bulb. The presence of multiple ulcers should raise the possibility of Zollinger-Ellison syndrome (see later, “[Zollinger-Ellison Syndrome](#)”).

Ulcer Healing and Scarring

Duodenal ulcers usually heal rapidly during treatment with antisecretory agents. As the ulcers decrease in size, they often have a linear configuration.^{66,104} Ulcer healing may lead to the development of an ulcer scar, manifested by radiating folds, bulbar deformity, or both. When radiating folds are present, they almost always converge at the site of the previous ulcer. In some patients, a residual depression in the central portion of the scar simulates an active ulcer crater. As a result, it is often difficult to differentiate small, healing ulcers from ulcer scars. Nevertheless, follow-up barium studies to demonstrate ulcer healing are probably unnecessary for patients with uncomplicated duodenal ulcers who have an adequate clinical response to medical therapy because these ulcers are almost always benign. Follow-up studies should therefore be reserved for patients with intractable ulcer symptoms or ulcer complications such as obstruction.

Bulbar deformity is caused by asymmetric scarring and retraction of the duodenal bulb during ulcer healing. Uninvolved segments of the bulb may balloon out between areas of fibrosis, producing one or more pseudodiverticula, which can usually be differentiated from ulcers by their tendency to change in size and shape at fluoroscopy. When multiple pseudodiverticula are present, the duodenal bulb may have a classic clover-leaf appearance (Fig. 29-33).

PYLORIC CHANNEL ULCERS

Pyloric channel ulcers should be treated as gastric ulcers rather than duodenal ulcers in terms of the need for aggressive evaluation and follow-up to differentiate these lesions from ulcerated carcinomas. Most pyloric channel ulcers are smaller than 1 cm and are located on the lesser curvature aspect of the pylorus. These ulcers tend to be located on the anterior wall of the pylorus, so they may appear as ring shadows on routine double-contrast views (Fig. 29-34A).¹¹⁵ In such cases, the ulcers should fill with barium on prone or upright compression views (Fig. 29-34B). Some pyloric channel ulcers may cause marked edema and spasm of the pylorus and distal antrum, so optimal radiologic evaluation of this area is not always possible.

Pyloric channel ulcers must be differentiated on barium studies from pseudodiverticula caused by scarring from previous ulcer disease or surgical pyloroplasty. However, ulcers usually have a fixed configuration, whereas pseudodiverticula are more likely to change in size and shape at fluoroscopy. The presence of folds in the region of the outpouching should also suggest a pseudodiverticulum rather than an ulcer. Occasionally, adult hypertrophic pyloric stenosis may be manifested by a narrowed, elongated pyloric channel with diamond-shaped outpouchings or dimples extending superiorly or inferiorly from this region, but these patients usually have a

Figure 29-29 Large postbulbar duodenal ulcers. A, B. Two patients with large postbulbar ulcers (arrows) in the proximal descending duodenum. In both cases, note marked narrowing of the adjacent duodenum proximally and distally (arrowheads) as a result of severe edema and spasm accompanying these ulcer craters. (From Carucci LR, Levine MS, Rubesin SE, et al: Upper gastrointestinal tract barium examination of postbulbar duodenal ulcers. *AJR* 182:927–930, 2004.)

long-standing history of obstructive symptoms. Healing of pyloric channel ulcers may lead to narrowing, elongation, or angulation of the pylorus, sometimes associated with gastric outlet obstruction.

Differential Diagnosis

Gastric or duodenal ulcers may occasionally be simulated by various double-contrast artifacts.¹¹⁶ An inadequate or poorly prepared barium suspension may result in the development of barium precipitates that resemble tiny ulcers in the stomach or duodenum. However, these precipitates can be differentiated from ulcers by their failure to project beyond the contour of the stomach or duodenum in profile and by the absence of associated findings such as mucosal edema or radiating folds. Stalactites are hanging droplets of barium that are sometimes seen on the anterior (nondependent) gastric wall.¹¹⁷ Although a stalactite can be mistaken for a small ulcer on a single view, the transient nature of this finding at fluoroscopy differentiates a stalactite from a true ulcer. Finally, calcified densities (e.g., renal calculi or calcified splenic arteries) or contrast-containing structures (e.g., colonic diverticula) overlying the stomach or duodenum can be mistaken for ulcers on double-contrast images. These artifacts are easily recognized by obtaining multiple images in different projections.

The most important consideration in the differential diagnosis of a benign gastric ulcer is an ulcerated gastric carcinoma (see earlier, “[Benign Versus Malignant Ulcers](#)”). An ulcer that is surrounded by a discrete mound of edema can also be mistaken for an ulcerated submucosal mass such as a gastrointestinal stromal tumor (GIST).^{118,119} However, the edematous mass surrounding an ulcer usually has poorly defined borders that form obtuse angles with the adjacent gastric wall, whereas a submucosal mass has well-defined borders that form right angles with the adjacent gastric wall.¹¹⁹ When gastric ulcers are associated with massive edema, there may be such narrowing and deformity that the radiographic findings erroneously suggest an infiltrating carcinoma. This problem is more likely to occur with prepyloric ulcers that cause gastric outlet obstruction, so it is not possible to adequately assess the distal antrum. If a malignant lesion cannot be excluded on radiologic criteria, endoscopy and biopsy should be performed for a more definitive diagnosis.

Although multiple gastric or duodenal ulcers may be present in patients with uncomplicated peptic ulcer disease, this finding should raise the possibility of Zollinger-Ellison syndrome, cytomegalovirus infection, caustic ingestion, lymphoma, and other granulomatous conditions such as Crohn’s disease, tuberculosis, sarcoidosis, and syphilis (see Chapters 30 and 33). In many cases, the correct diagnosis is suggested by the clinical history.

Figure 29-30 Postbulbar ring stricture. There is eccentric narrowing (arrow) of the postbulbar duodenum secondary to scarring and fibrosis from a previous ulcer in this location. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 29-31 Giant duodenal ulcer. This giant ulcer (arrows) has replaced almost the entire duodenal bulb. Paradoxically, such ulcers can be mistaken for a scarred or even normal bulb.

Figure 29-32 Giant duodenal ulcer. Four spot images of the bulb show a giant ulcer that has a constant size and shape. In contrast, the duodenal bulb usually has a changing appearance at fluoroscopy. Also note the large radiolucent band of edema adjacent to the ulcer.

Figure 29-33 Scarred duodenal bulb. **A, B.** Two examples of marked bulbar deformity with multiple pseudodiverticula, producing a cloverleaf appearance.

Figure 29-34 Pyloric channel ulcer. **A.** Initial double-contrast view with the patient in a supine position shows a partial ring shadow (arrow) in the region of the pylorus. **B.** Prone compression view shows barium filling an ulcer crater (arrow) on the anterior wall of the pyloric channel.

Gastric ulcer scars that are manifested by radiating folds must be differentiated from early gastric cancers in which the folds tend to have a more lobulated, nodular, or irregular appearance.¹⁰⁰ If the radiographic findings are equivocal, endoscopy and biopsy should be performed for a more certain diagnosis. Benign-appearing ulcer scars may also result from healing of lymphomatous gastric lesions treated with chemotherapy (see Chapter 33).¹²⁰ Finally, ulcer scars may resemble surgical scars resulting from prior gastrectomy, cystogastrectomy (internal drainage of a pancreatic pseudocyst into the stomach), or wedge resection of the stomach,⁹² but ulcer scars can usually be differentiated from surgical scars on the basis of the clinical history.

Approach to Ulcers

In view of current recommendations that all *H. pylori*-positive patients with gastric or duodenal ulcers be treated with

antimicrobial and antisecretory agents,^{52,53} it is important to determine whether patients with ulcers are infected with *H. pylori*. Although endoscopy and biopsy may be performed to document the presence of this infection, highly accurate noninvasive tests for *H. pylori*, such as a urea breath test and serologic test, are widely available (see Chapter 30). The combination of a double-contrast upper GI study and noninvasive testing for *H. pylori* could therefore replace endoscopy as a reasonable approach for evaluating patients with dyspepsia, epigastric pain, or other upper GI symptoms.⁸

Here is one scenario. Patients with persistent upper GI symptoms who fail to respond to an empiric trial of antisecretory agents could undergo a double-contrast barium study as the first diagnostic examination. If the barium study reveals a gastric or duodenal ulcer, a noninvasive test for *H. pylori* could be performed to determine whether the patient should receive antibiotics and conventional antisecretory agents. If the barium study reveals gastritis or duodenitis without an ulcer, however,

there is not yet enough evidence to justify treatment with antibiotics, even if these patients are infected with *H. pylori* (see Chapter 30). Thus, testing for *H. pylori* would not be required in most cases. Finally, if the barium study reveals a suspicious gastric ulcer or any abnormality that is equivocal or suspicious for malignant tumor, endoscopy should be performed for a more definitive diagnosis.

If randomized, controlled trials ultimately reveal that symptomatic patients with *H. pylori* gastritis should be treated with antimicrobial agents in the absence of ulcers, noninvasive tests for *H. pylori* could be performed routinely at the time of the initial barium study. Clinical decisions regarding treatment with antisecretory agents or antibiotics could then be made on the basis of the combined results of the barium study and noninvasive tests for *H. pylori*. Nevertheless, endoscopy would still be required for any patients with equivocal or suspicious radiographic findings.

Complications

The major complications of peptic ulcers include upper GI bleeding, obstruction, and perforation. Such events can be life-threatening, so early diagnosis and treatment of these complications are essential for decreasing the morbidity and mortality in patients with peptic ulcers.

UPPER GASTROINTESTINAL BLEEDING

Endoscopy has a sensitivity of more than 90% in detecting the site of hemorrhage in patients with bleeding peptic ulcers.¹²¹ Barium studies are less accurate because of the difficulty obtaining adequate mucosal coating in the presence of bleeding and the inability to determine whether a radiographically diagnosed lesion is the actual source of bleeding. Nevertheless, double-contrast studies can detect the bleeding site in 70% to 80% of patients with acute upper GI hemorrhage.^{121,122}

The most frequent radiologic sign of bleeding in a gastric or duodenal ulcer is a blood clot at the base of the ulcer, typically seen as a smooth or irregular filling defect in the barium-filled ulcer crater (Fig. 29-35).¹²² Although granulation tissue or debris in the ulcer may produce similar findings, the defect is likely to represent an adherent blood clot in patients with a history of recent upper GI bleeding. If the clot is dislodged, recurrent bleeding may result in potentially catastrophic consequences. These patients should therefore be observed carefully for 24 to 48 hours when a blood clot is detected on barium studies.

OBSTRUCTION

Although ulcers in the fundus, body, or proximal antrum of the stomach rarely cause gastric outlet obstruction, ulcers in the distal antrum, pyloric channel, or duodenum may cause obstruction secondary to edema and spasm associated with the ulcer crater or scarring and fibrosis associated with ulcer healing. In patients with severe gastric outlet obstruction, abdominal radiographs may reveal a dilated stomach containing food and debris (Fig. 29-36A). This food or fluid in the stomach may dilute ingested barium, compromising the radiographic examination (Fig. 29-36B). The stomach should therefore be decompressed with a nasogastric tube before performing barium studies on these patients.

Figure 29-35 Ulcer with blood clot. A radiolucent filling defect is seen in the central portion of a barium-filled ulcer (arrow) on the posterior wall of the stomach. This patient presented with hematemesis 1 day earlier. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Severe scarring from ulcers in the distal antrum or pyloric channel may be manifested on barium studies by a relatively short segment of narrowing with delayed emptying of barium from the stomach (see Fig. 29-19A). It is sometimes difficult to differentiate areas of scarring from a localized scirrhous carcinoma involving the prepyloric region of the antrum,¹²³ but irregular narrowing and abrupt, shelflike proximal borders should favor a malignant lesion (see Chapter 32). If the findings are equivocal or suspicious for tumor, endoscopy and biopsy should be performed for a more definitive diagnosis.

Although scarring from duodenal bulb ulcers rarely causes obstruction, postbulbar ulcers may lead to obstructing strictures in the proximal descending duodenum (see earlier, “**Postbulbar Ulcers**”). Other causes of duodenal narrowing and obstruction include Crohn’s disease, tuberculosis, tumors, hematomas, duplication cysts, and extrinsic compression of the duodenum by an annular pancreas, pancreatitis, pancreatic pseudocyst, or pancreatic carcinoma.

PERFORATION

Penetrating ulcers on the anterior wall of the stomach or duodenum may perforate directly into the peritoneal cavity, whereas penetrating ulcers on the posterior wall of the stomach or duodenum usually result in a walled-off or confined perforation. Some penetrating ulcers may also involve other hollow organs, producing a fistula. These various types of perforations are considered separately in the following sections.

Free Perforation

Ulcers on the anterior wall of the stomach or duodenum directly abut the peritoneal cavity, so perforation of a penetrating ulcer

Figure 29-36 Gastric outlet obstruction caused by pyloric channel ulcers. **A.** Abdominal radiograph shows a markedly dilated stomach with retained food and debris caused by gastric outlet obstruction. After the stomach was decompressed, endoscopy revealed a pyloric channel ulcer causing the obstruction. **B.** In another patient, an overhead radiograph from a barium study shows a dilated stomach with retained fluid diluting the barium and no emptying into the duodenum. A large pyloric channel ulcer (arrow) is also seen.

in this location may result in acute peritonitis with free spillage of gastric and duodenal contents into the peritoneal cavity. Because duodenal ulcers are often located on the anterior wall of the bulb, a perforated duodenal ulcer is the most common cause of peritonitis in the adult population. The volume of gas that escapes into the peritoneal cavity from a perforated ulcer depends on how quickly the site of perforation seals off. In one study, free intraperitoneal air was detected on abdominal radiographs in only about two thirds of patients with perforated duodenal ulcers.¹²⁴ Thus, the presence of pneumoperitoneum in an acutely ill patient strongly supports the diagnosis of a perforated ulcer, but the absence of pneumoperitoneum in no way excludes this diagnosis.

If abdominal radiographs reveal pneumoperitoneum in patients with clinical signs of peritonitis, immediate surgery is warranted. If there is no evidence of pneumoperitoneum, studies with water-soluble contrast agents or computed tomography (CT) may be performed to determine whether a perforation has occurred. Only about 50% of patients with perforated duodenal ulcers are found to have extravasation of contrast medium from the duodenum, presumably because the perforation has sealed off by the time the examination is performed.¹²⁵ When extravasation of contrast medium does occur, about 50% of patients are found to have a generalized leak into the peritoneal cavity and 50% are found to have a walled-off leak (Fig. 29-37)¹²⁵ (see later, “[Confined Perforation](#)”).

When an ulcer causes free perforation, studies with water-soluble contrast agents may show contrast medium leaking from the stomach or duodenum into the subhepatic space or elsewhere into the peritoneal cavity. CT may reveal inflammatory changes in the soft tissues abutting the stomach and duodenum, extraluminal fluid or contrast material, and varying amounts of free intraperitoneal air.¹²⁶ The site of perforation

can sometimes be identified on CT by interruption of the enhanced gastroduodenal wall or by tiny extraluminal air bubbles in close proximity to the perforation.¹²⁷

Less frequently, ulcers on the posterior wall of the stomach may perforate into the lesser peritoneal cavity, or lesser sac, a potential space between the stomach and pancreas. An abscess in the lesser sac may be manifested by extraluminal gas collections in the left upper quadrant on abdominal radiographs (Fig. 29-38) or by extrinsic mass effect on the posterior wall of the stomach or actual leakage of contrast material into the lesser sac on studies with water-soluble contrast agents. CT is extremely useful for documenting these lesser sac collections or abscesses.¹²⁸

Confined Perforation

Penetrating ulcers on the posterior wall of the stomach or duodenum are often associated with the development of a walled-off or confined perforation secondary to an inflammatory reaction and fibrous adhesions that seal off the perforation site as the ulcer enters adjacent structures. The pancreas is involved in most patients with confined perforations. Other less common sites of involvement include the lesser omentum, transverse mesocolon, liver, spleen, biliary tract, and colon. If the affected structure is a hollow organ such as the colon or biliary tract, this process may lead to the development of a fistula (see later, “[Fistulas](#)”).

Less than 50% of patients with posterior penetrating ulcers and confined perforations have evidence of extraluminal gas or contrast medium collections on studies with water-soluble contrast agents. A posterior penetrating ulcer should be suspected, however, when an unusually deep ulcer crater is seen in profile on the posterior wall of the stomach or duodenum. In such cases, CT may be helpful for demonstrating signs of pancreatic penetration, including loss of fascial planes and the presence of

Figure 29-37 Perforated duodenal ulcer. Water-soluble contrast medium is seen tracking superiorly from the region of the duodenal bulb into a sealed-off collection (arrow). This patient presented with clinical signs of peritonitis.

Figure 29-38 Lesser sac abscess caused by a perforated gastric ulcer. Upright abdominal radiograph shows an air-fluid level (arrow) in the lesser sac caused by a lesser sac abscess. Subsequent study with a water-soluble contrast agent revealed a perforated posterior wall gastric ulcer with leakage of the contrast agent directly into the lesser sac.

soft tissue bands or low-density sinus tracks between these structures.¹²⁹

Penetrating ulcers on the lesser curvature of the stomach may occasionally enter the adjacent hepatic parenchyma, resulting in the development of an abscess in the left lobe of the liver. This complication should be suspected when contrast studies demonstrate a deep ulcer on the lesser curvature associated with a large area of extrinsic mass effect on the adjacent gastric wall (Fig. 29-39A). In such cases, CT can be used to confirm the presence of a confined perforation involving the liver (Fig. 29-39B).

Splenic penetration by a gastric ulcer is extremely unusual because of the rarity of benign ulcers on the posterior wall or greater curvature of the gastric fundus. Although barium studies are usually nonspecific, transmural penetration by an ulcer high on the greater curvature or posterior wall of the stomach may be suspected if the ulcer extends well beyond the adjacent gastric contour.¹³⁰ In such cases, CT may demonstrate extension of the ulcer directly into the substance of the spleen.¹³¹ If CT confirms splenic penetration by a benign gastric ulcer, early surgery is required because of the risk of massive, potentially life-threatening GI bleeding if the ulcer ruptures into the spleen.¹³¹

Fistulas

Penetrating ulcers in the stomach or duodenum may occasionally erode through the wall of adjacent hollow organs, producing a variety of fistulas, including gastroduodenal, gastroduodenal, gastroduodenal, choledochoduodenal, duodenorenal,

and gastropericardial fistulas. These fistulas are considered separately in the following sections.

Gastroduodenal Fistulas (Double-Channel Pylorus). The double-channel pylorus is an acquired gastroduodenal fistula caused by a penetrating ulcer in the distal antrum that erodes directly into the base of the duodenal bulb.¹³²⁻¹³⁴ These ulcers are usually located on the lesser curvature of the prepyloric antrum but are occasionally located on the greater curvature.^{133,134} Paradoxically, the development of a double-channel pylorus may lead to improved ulcer symptoms, possibly because the fistula facilitates gastric emptying.¹³⁴

Although the double-channel pylorus is difficult to visualize on endoscopy, it is readily detected on barium studies.^{133,134} The double-channel pylorus is typically manifested by two discrete tracks extending from the distal antrum into the base of the duodenal bulb (Fig. 29-40). The track on the greater curvature side of the stomach usually represents the true pyloric channel, whereas the track on the lesser curvature side represents the fistula. The barium-filled tracks are often separated by a thin radiolucent bridge or septum that is best seen on prone compression views. Sequential barium studies may show progression from a penetrating prepyloric ulcer to a double-channel pylorus.

Gastrocolic Fistulas. In the past, most gastrocolic fistulas were thought to be caused by primary carcinoma of the stomach or transverse colon invading the gastrocolic ligament.¹³⁵ With the

Figure 29-39 Penetrating lesser curvature ulcer with an associated hepatic abscess. **A.** Barium study shows a deep ulcer (curved arrow) on the lesser curvature of the distal antrum. Also note the large area of extrinsic mass effect (straight arrows) on the adjacent gastric wall. **B.** CT scan reveals several gas- and fluid-containing abscess cavities (arrows) in the left lobe of the liver. These abscesses were caused by penetration of the ulcer into the hepatic parenchyma.

increasing use of aspirin and other NSAIDs in today's pill-oriented society, however, benign NSAID-induced ulcers on the greater curvature of the stomach have become a more common cause of gastrocolic fistulas than carcinoma of the stomach or transverse colon.^{78,136-138} Affected individuals typically have a history of taking high doses of aspirin or other NSAIDs. As the ulcers enlarge, they penetrate inferiorly into the gastrocolic ligament, eventually producing a gastrocolic fistula. These fistulas are classically manifested by the triad of feculent vomiting, foul-smelling eructations, and diarrhea,¹³⁵ but some patients may present with abdominal pain or other nonspecific clinical findings.¹³⁷ When a gastrocolic fistula is suspected on clinical grounds, endoscopy is contraindicated because of the risk of perforation and peritonitis.¹³⁶ In contrast to gastrocolic fistulas caused by malignant tumors, fistulas complicating NSAID-induced greater curvature ulcers sometimes heal on medical therapy without need for surgery.^{137,139}

In patients with gastrocolic fistulas complicating NSAID-induced ulcers, barium studies may reveal giant ulcers on the greater curvature of the gastric antrum or body with early filling of the transverse colon via the fistula (Fig. 29-41).^{136,137} Because of the greater pressures generated during a barium enema examination, this technique can sometimes demonstrate fistulas that are not visualized on upper GI studies.¹³⁸ When fistulas are shown on barium studies, patients should be questioned about a possible history of NSAID use. Other causes of gastrocolic fistulas include gastric or colonic carcinoma, lymphoma, Crohn's disease, and tuberculosis.

Duodenocolic Fistulas. Duodenocolic fistulas are usually caused by carcinoma of the ascending colon or hepatic flexure invading the descending duodenum. Occasionally, these fistulas may result from penetrating ulcers in the duodenal bulb or postbulbar duodenum that have eroded into the hepatic flexure of the colon.^{140,141} Affected individuals may present with abdominal pain, diarrhea, feculent vomiting, foul-smelling

Figure 29-40 Double channel pylorus. **A.** Double-contrast view of the antrum shows a prepyloric lesser curvature ulcer (curved arrow) that communicates distally with the base of the duodenal bulb (straight arrow). **B.** Prone view of the antrum also delineates the lesser curvature ulcer (curved arrow) with a track (straight arrow) extending from the ulcer into the duodenum. Note the normal pyloric channel (open arrow) inferiorly.

Figure 29-41 Gastrocolic fistula caused by an aspirin-induced greater curvature ulcer. Double-contrast upper GI study reveals a giant ulcer (large arrow) on the greater curvature of the stomach, with barium entering a wide fistulous track (small arrows) that communicates directly with the transverse colon. This patient had been on high doses of aspirin. (From Levine MS, Kelly MR, Laufer I, et al: *Gastrocolic fistulas: The increasing role of aspirin*. *Radiology* 187:359–361, 1993.)

eructations, or undigested food in the stool. Although upper GI studies may fail to demonstrate the fistula, barium enema examinations are often successful because of the greater pressures generated by this technique.¹⁴¹

Choledochoduodenal Fistulas. About 90% of enterobiliary fistulas occur as complications of stones in the biliary tract; only about 5% are caused by peptic ulcer disease.¹⁴² Most of the latter patients have penetrating duodenal ulcers that rupture into the common bile duct, producing a choledochoduodenal fistula.¹⁴² These patients usually have symptoms related to their underlying ulcers but occasionally present with abnormal liver function tests, jaundice, or ascending cholangitis.¹⁴³ Abdominal radiographs may reveal pneumobilia with gas in the gallbladder or bile ducts (Fig. 29-42), and barium studies may demonstrate a duodenal ulcer or duodenal scarring, sometimes associated with reflux of barium into the biliary tree.^{143–145} Rarely, these ulcers may lead to the development of cholecystoduodenal, cholecystogastric, or choledochogastric fistulas.¹⁴²

Duodenorenal Fistulas. Penetrating postbulbar duodenal ulcers rarely may rupture posteriorly into the pyelocalyceal system of the right kidney, producing a duodenorenal fistula. These fistulas may be demonstrated on barium studies or retrograde pyelography. Other rare causes of duodenorenal fistulas include malignant tumors, infection, and trauma.

Gastropericardial Fistulas. Ulcers in the intrathoracic portion of the stomach (a hiatal hernia or gastric pull-through after

Figure 29-42 Pneumobilia caused by a choledochoduodenal fistula. Close-up view from an abdominal radiograph shows gas in the gallbladder (straight arrow) and bile ducts (curved arrow) secondary to a choledochoduodenal fistula in a patient with a giant duodenal ulcer.

esophagogastrectomy) rarely may erode through the pericardium, producing a gastropericardial fistula.¹⁴⁶ This complication is catastrophic for the patient because it usually leads to the rapid development of purulent pericarditis, cardiac tamponade, and death. The sudden appearance of pneumopericardium on chest radiographs of an acutely ill patient with an intrathoracic stomach should raise the possibility of a gastropericardial fistula. Upper GI studies with water-soluble contrast agents may document the presence of a fistula by showing extravasation of contrast medium into the pericardial sac.¹⁴⁷ Because of the high mortality associated with this complication, the best hope for survival is early surgery with drainage of the pericardium and closure of the fistula.¹⁴⁶

Zollinger-Ellison Syndrome

Since its original description by Zollinger and Ellison in 1955,¹⁴⁸ Zollinger-Ellison syndrome has been recognized as a life-threatening condition characterized by marked hypersecretion of gastric acid and a severe form of peptic ulcer disease secondary to high levels of gastrin in patients with underlying gastrinomas. These tumors not only may cause a devastating ulcer diathesis but may also behave as malignant lesions, metastasizing to the liver or other structures (see Chapter 98). The development of potent antisecretory agents for controlling acid secretion and sophisticated techniques for localizing these islet

cell tumors have had a major impact on patient survival. Although barium studies may reveal typical findings of peptic ulcer disease, it is sometimes possible to suggest the diagnosis of Zollinger-Ellison syndrome on the basis of the radiographic findings.

PATHOLOGY

Zollinger-Ellison syndrome is caused by the uncontrolled release of gastrin from autonomously functioning non- β islet cell tumors, also known as gastrinomas (see Chapter 98). About 75% of these tumors are located in the pancreas, 15% in the duodenum, and 10% in other extraintestinal locations such as the liver, ovaries, and lymph nodes.^{149,150} Most gastrinomas are thought to be malignant; metastases are found at the time of diagnosis in 30% to 50% of patients.¹⁵⁰ The liver is the most frequent site of metastatic disease.

Most gastrinomas occur sporadically, but 25% of these tumors are transmitted as part of a hereditary syndrome (multiple endocrine neoplasia type 1).¹⁵¹ This syndrome is characterized not only by pancreatic tumors but also by parathyroid, pituitary, and adrenal tumors.

CLINICAL ASPECTS

More than 90% of patients with Zollinger-Ellison syndrome have upper GI ulcers caused by hypersecretion of gastric acid.¹⁵⁰ The presenting signs and symptoms may be indistinguishable from those associated with ordinary peptic ulcers. However, the possibility of Zollinger-Ellison syndrome should be considered in patients who have multiple ulcers, ulcers in unusual locations, ulcers that are resistant to medical therapy, or recurrent ulcers postoperatively.^{149,150}

The second most common clinical problem in Zollinger-Ellison syndrome is diarrhea, which occurs in up to 50% of patients and is the presenting symptom in 35%.^{149,150} This diarrhea is related primarily to the severe volume load caused by the secretion of several liters of acid into the intestines each day. The acidic pH of the small bowel may also damage the intestinal mucosa, resulting in a spruelike state with villous atrophy, malabsorption, and steatorrhea.¹⁵² Other patients may initially present with reflux symptoms or dysphagia secondary to the development of severe reflux esophagitis or peptic strictures.¹⁵³

The diagnosis of Zollinger-Ellison syndrome is established by the demonstration of hypergastrinemia and gastric acid hypersecretion in a patient with peptic ulcers, diarrhea, or other clinical features of a gastrinoma. In the appropriate clinical setting, fasting serum gastrin levels higher than 1000 pg/mL should be virtually diagnostic of Zollinger-Ellison syndrome.¹⁵⁰ However, not all patients have such high serum gastrin levels. Furthermore, hypergastrinemia may occur in patients with atrophic gastritis, gastric outlet obstruction, and G-cell hyperplasia.

In the past, total gastrectomy was the treatment of choice for preventing hypersecretion of acid and its complications in patients with Zollinger-Ellison syndrome. However, H₂ receptor antagonists (e.g., cimetidine, ranitidine) and proton pump inhibitors (e.g., omeprazole) have proved to be extremely effective in suppressing acid secretion and promoting ulcer healing without need for surgery.^{150,154,155} A total gastrectomy should therefore be reserved for noncompliant patients.

As fewer patients succumb to the ulcer diathesis in Zollinger-Ellison syndrome, malignant spread of gastrinomas has become a major cause of long-term morbidity and mortality in these individuals. Greater attention has therefore been focused on early detection and excision of the gastrinomas before the development of hepatic metastases.^{156,157} Although the primary tumors are often difficult to detect on preoperative imaging studies, successful localization of gastrinomas can be achieved by CT, angiography, or selective portal venous sampling for gastrin or by whole-body imaging with somatostatin scintigraphy.¹⁵⁸⁻¹⁶¹ The most important prognostic factor affecting survival is the extent of tumor at the time of surgery. Patients with no tumor or lesions that are resectable at laparotomy have 5-year survival rates higher than 90%, whereas patients with liver metastases have 5-year survival rates less than 20%.¹⁵⁰

RADIOGRAPHIC FINDINGS

Zollinger-Ellison syndrome may be manifested on barium studies by a characteristic constellation of findings.¹⁶²⁻¹⁶⁶ Hypersecretion of acid often results in a large volume of fluid in the stomach, duodenum, and proximal jejunum that dilutes ingested barium and compromises the mucosal coating. Many patients have markedly thickened gastric folds, particularly in the fundus and body of the stomach, not only because of edema and inflammation but also because of gastrin-induced parietal cell hyperplasia (Fig. 29-43A). Duodenal and jejunal folds may also have a grossly thickened, edematous appearance because of a severe inflammatory response to the enormous volume of gastric secretions entering the small bowel. Although thickened folds may be caused by a variety of conditions in the stomach and duodenum (see later, “Differential Diagnosis”), the combination of thickened folds and excessive fluid in the stomach, duodenum, and proximal jejunum should suggest the possibility of Zollinger-Ellison syndrome.

Approximately 75% of the ulcers in Zollinger-Ellison syndrome are located in the stomach or duodenal bulb, so they cannot be differentiated from uncomplicated peptic ulcers.¹⁶⁷ The remaining 25% are located in the postbulbar duodenum or proximal jejunum.¹⁶⁷ Because peptic ulcers rarely occur distal to the papilla of Vater, the presence of one or more ulcers in the third or fourth portion of the duodenum or even the proximal jejunum should be highly suggestive of Zollinger-Ellison syndrome (Fig. 29-43B). Patients with this syndrome are also more likely to have multiple ulcers than other patients with peptic ulcer disease.¹⁶⁷

DIFFERENTIAL DIAGNOSIS

Markedly thickened gastric folds may be present in a variety of conditions, including *H. pylori* gastritis, hypertrophic gastritis, Ménétrier's disease, and lymphoma. Similarly, thickened duodenal or jejunal folds may be caused by inflammatory or infectious processes. Although thickened folds are a nonspecific finding, the simultaneous presence of increased fluid in the upper GI tract and one or more ulcers in unusual locations should strongly suggest Zollinger-Ellison syndrome. If this syndrome is suspected on the basis of the radiographic findings, a fasting serum gastrin level should be obtained for a more definitive diagnosis.

Figure 29-43 Zollinger-Ellison syndrome. **A.** There are markedly thickened folds in the gastric fundus and body. Also note how the barium is diluted by excessive fluid in the stomach. **B.** In another patient, two discrete ulcers (arrows) are seen in the third and fourth portions of the duodenum. Ordinary peptic ulcers rarely occur distal to the papilla of Vater, so ulcers in this location should suggest the possibility of Zollinger-Ellison syndrome. (**B** courtesy Stephen W. Trenkner, MD, Minneapolis.)

Erosive Gastritis

Erosions are defined histologically as epithelial defects that do not penetrate beyond the muscularis mucosae. Although erosive gastritis is rarely diagnosed on conventional single-contrast barium studies, it has become a relatively frequent finding on double-contrast studies, with an overall prevalence of 0.5% to 20% reported in the radiology literature.¹⁻⁶ However, not all patients with erosive gastritis are symptomatic. As a result, it is difficult to be certain of the clinical importance of gastric erosions demonstrated on radiologic or endoscopic examinations.

PATHOGENESIS

Aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs) are thought to be the most common cause of erosive

gastritis, accounting for about 50% of cases.⁷ Other causes include alcohol, stress, trauma, burns, Crohn's disease, viral or fungal infection, and endoscopic heater probe therapy or other iatrogenic trauma.⁸⁻¹³ Still other patients with erosive gastritis have no apparent predisposing factors for this condition.¹⁴ These cases presumably occur as a variant of peptic ulcer disease.

Considerable attention has been focused on the role of aspirin and other NSAIDs in the development of erosive gastritis. Clinical and laboratory investigations have shown that these agents are capable of disrupting the mucosal barrier in the stomach, causing erosive gastritis and gastric ulcers (see Chapter 29).^{8,15-18} In one study, 40% of patients receiving aspirin for 3 months or longer had endoscopic evidence of erosive gastritis.¹⁶ Other studies on healthy volunteers have shown that as few as two aspirin tablets may cause acute erosive gastritis that is recognized on endoscopy within 24 hours.^{17,18} Maximal damage

usually occurs within 1 to 3 days, and healing may be documented on endoscopy within 1 week.¹⁹ Thus, gastric erosions may form rapidly after ingestion of aspirin or other NSAIDs and may heal rapidly when these drugs are withdrawn.

CLINICAL FINDINGS

Patients with erosive gastritis may present with dyspepsia, epigastric pain, or signs of upper gastrointestinal (GI) bleeding.²⁰ However, other patients are asymptomatic. Gastric erosions can persist for years in the absence of clinical symptoms.²¹ Because erosions may be detected as an incidental finding on barium studies or endoscopy, it is important to rule out other abnormalities in the stomach before assuming that these erosions are the cause of the patient's symptoms.

RADIOGRAPHIC FINDINGS

Two types of erosions may be detected on double-contrast studies. The most common type is the complete or varioliform

erosion in which punctate or slitlike collections of barium representing the epithelial defects are surrounded by radiolucent halos of edematous, elevated mucosa (Fig. 30-1).^{3,5,14} Varioliform erosions typically occur in the gastric antrum and are often aligned on the crests of the rugal folds.^{3,5,20} Because they are shallow lesions, erosions on the posterior (dependent) wall may be better delineated by flow technique to manipulate a thin layer of barium over the dependent mucosal surface.²² The surrounding mounds of edema may prevent filling of the central pits or depressions, so these erosions sometimes appear as filling defects in the thin barium pool without central collections of barium. In other patients, erosive gastritis may be manifested only by scalloped antral folds (Fig. 30-2A). Depending on the quality of mucosal coating, erosions may be faintly seen on the crest of the folds (Fig. 30-2B). These scalloped antral folds often persist after the erosions have healed. Residual epithelial nodules or polyps may occasionally be detected at the site of the healed erosions. These hyperplastic polyps are thought to represent the sequelae of chronic erosive gastritis.²⁰

Figure 30-1 Erosive gastritis with varioliform erosions.
A, B. In both patients, multiple varioliform erosions are seen in the antrum as tiny barium collections with surrounding halos of edematous mucosa. (**A** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 30-2 Erosive gastritis with scalloped antral folds.
A. A thickened, scalloped fold is present in the gastric antrum.
B. In another patient, several erosions (arrows) can be seen on the crest of a scalloped fold.

Figure 30-3 Erosive gastritis with incomplete erosions. Numerous linear and punctate erosions are seen in the gastric antrum and body. Many of the erosions are incomplete (i.e., they are not surrounded by radiolucent mounds of edema).

Incomplete or flat erosions are epithelial defects that are not associated with elevation of the surrounding mucosa. These erosions appear as linear streaks or dots of barium (Fig. 30-3).^{6,14} Because the surrounding mucosa is normal, incomplete erosions are much more difficult to detect than varioliform erosions, accounting for only 5% to 19% of all erosions found on double-contrast studies.^{6,7}

Although no causative significance is generally attributed to the shape or location of gastric erosions seen on double-contrast studies, aspirin and other NSAIDs may occasionally produce incomplete, linear or serpiginous erosions that tend to be clustered in the body of the stomach on or near the greater curvature (Fig. 30-4).²³ It has been postulated that these erosions result from localized mucosal injury as the dissolving capsules or tablets collect by gravity in the dependent portion of the stomach. Whatever the explanation, these distinctive linear or serpiginous erosions should be highly suggestive of recent aspirin or other NSAID use. Nevertheless, most patients with NSAID-induced erosive gastritis have typical varioliform erosions in the gastric antrum.^{7,23} Aspirin or other NSAIDs should therefore be considered the most likely cause of erosive gastritis, even when the erosions have a varioliform appearance.

Recurrent episodes of NSAID-induced erosion formation and healing may eventually lead to relatively subtle flattening and deformity of the greater curvature of the antrum, a radiologic sign of NSAID-related gastropathy (Fig. 30-5).^{24,25} Detection of gastric erosions or greater curvature flattening should therefore lead to careful questioning of the patient about a possible history of aspirin or other NSAID use. If recent ingestion of these drugs is confirmed in symptomatic patients,

Figure 30-4 Erosive gastritis caused by nonsteroidal anti-inflammatory drugs. A, B. Distinctive linear and serpiginous erosions are clustered in the body (A) and antrum (B) of the stomach near the greater curvature as a result of NSAID ingestion. The patient in A was taking naproxen, and the patient in B was taking ibuprofen. (A from Levine MS, Verstandig A, Laufer I: *Serpiginous gastric erosions caused by aspirin and other nonsteroidal antiinflammatory drugs*. AJR 146:31–34, 1986.)

Figure 30-5 Antral flattening caused by NSAIDs. There is flattening and deformity of the greater curvature of the distal antrum (arrow) as a result of chronic aspirin therapy. This finding is characteristic of NSAID-related gastropathy.

withdrawal of the offending agent usually produces a marked clinical response.²³

Crohn's disease is another condition that can be manifested on double-contrast studies by multiple erosions or aphthoid ulcers in the stomach.^{10,11} However, these patients usually have associated Crohn's disease involving the small bowel or colon (see later, "[Crohn's Disease](#)"). Shallow ulcers or erosions may also result from opportunistic infection by cytomegalovirus (CMV) in patients with AIDS (see later, "[Cytomegalovirus](#)"),²⁶ or they may occur as a complication of endoscopic heater probe therapy or other iatrogenic trauma ([Fig. 30-6](#)).¹³

DIFFERENTIAL DIAGNOSIS

Gastric erosions can sometimes be mistaken on barium studies for ulcerated submucosal masses or bull's-eye lesions in the stomach. However, the central ulcer of a bull's-eye lesion is considerably larger than an erosion, and the surrounding mass tends to be larger than the radiolucent mound of edema surrounding an erosion (see Chapter 33). Bull's-eye lesions also tend to be more sporadic than erosions and are not typically aligned on the crests of the folds. As a result, it is almost always possible to distinguish these lesions by radiographic criteria.

Antral Gastritis

Some patients have a form of gastritis that is confined to the gastric antrum, an entity also known as *antral gastritis*. Alcohol, tobacco, coffee and, more recently, *Helicobacter pylori* have been implicated in the development of antral gastritis (see later, "[Helicobacter pylori Gastritis](#)"). Some patients with this

Figure 30-6 Heater probe ulcers and erosions. Shallow, irregular ulcers and linear erosions are seen en face (white arrows) and in profile (black arrow) on the greater curvature of the stomach. These ulcerations occurred as a direct complication of endoscopic heater probe therapy. (From Rummerman J, Rubesin SE, Levine MS, et al: *Gastric ulceration caused by heater probe coagulation*. *Gastrointest Radiol* 13:200–202, 1988.)

condition have increased secretion of peptic acid, but others have normal or even decreased acid secretion. Affected individuals may present with dyspepsia, epigastric pain, or other symptoms indistinguishable from those of peptic ulcer disease. Treatment is generally aimed at suppressing acid secretion in the stomach.

RADIOGRAPHIC FINDINGS

Antral gastritis may be manifested on barium studies by thickened folds, antral erosions (see earlier, "[Erosive Gastritis](#)"), crenulation of the lesser curvature, mucosal nodularity, transverse antral striae, a hypertrophied antral-pyloric fold, and antral narrowing. Some patients have thickened, scalloped, or lobulated folds that are oriented longitudinally in the antrum ([Fig. 30-7A](#)), whereas others have thickened transverse antral folds ([Fig. 30-7B](#)). Thickened folds, which are detected radiographically in about 75% of cases, should be recognized as the single most common sign of antral gastritis on barium studies.⁷ The vast majority of these patients are found to have *H. pylori* as the cause of their gastritis (see later, "[Helicobacter pylori Gastritis](#)").⁷

Crenulation or irregularity of the lesser curvature of the distal antrum may also be recognized as a sign of antral gastritis on barium studies (see [Fig. 30-7B](#)).²⁷ Other patients may have fine transverse striations, or antral striae, as a sign of chronic antral gastritis,²⁸ although this finding can also be seen as a normal variant.²⁹ Still other patients may have a single lobulated fold that arises on the lesser curvature of the prepyloric antrum and extends into the pylorus or base of the duodenal bulb ([Fig. 30-8](#)).^{30,31} This so-called hypertrophied

Figure 30-7 Antral gastritis. **A.** This patient has thickened scalloped folds that are oriented longitudinally in the antrum. **B.** In another patient, there are thickened transverse folds in the antrum with fine nodularity and crenulation of the adjacent lesser curvature (arrows).

Figure 30-8 Hypertrophied antral-pyloric fold. **A, B.** In both patients, there is a smooth, slightly lobulated fold (arrows) on the lesser curvature of the distal antrum extending through the pylorus into the base of the duodenal bulb. The characteristic appearance and location of this fold should differentiate it from a polypoid or plaque-like antral carcinoma.

antral-pyloric fold is thought to be a sequela of chronic antral gastritis and is often associated with other radiographic signs of gastritis. Endoscopy is not warranted when a characteristic antral-pyloric fold is seen on barium studies.³¹ If the fold is more lobulated and cannot be distinguished from a polypoid or plaque-like carcinoma on the lesser curvature, however, endoscopy and biopsy should be performed to rule out malignant tumor.

DIFFERENTIAL DIAGNOSIS

Severe antral gastritis associated with antral narrowing must be differentiated from gastric carcinoma. With malignant tumors, however, the narrowed antrum tends to have a more abrupt transition with the adjacent stomach and a more fixed, rigid contour. Thus, it is usually possible to differentiate these

conditions by radiographic criteria. When the folds are markedly thickened and lobulated, antral gastritis can also mimic the appearance of lymphoma or even a submucosally infiltrating carcinoma.³² In such cases, endoscopy may be required for a more definitive diagnosis.

Helicobacter pylori Gastritis

H. pylori (formerly known as *Campylobacter pylori*) is a gram-negative bacillus that was first isolated from the stomach by Warren and Marshall in 1983.³³ Since then, *H. pylori* has been recognized as the most common cause of chronic active gastritis.^{34,35} The organism is usually found in clusters or clumps beneath the mucous layer on surface epithelial cells or, less commonly, superficial foveolar cells in the stomach.³⁶ *H. pylori* gastritis is characterized pathologically by an acute inflammatory

reaction in the mucosa with accumulation of neutrophils, plasma cells and, eventually, lymphoid nodules.³⁶ The gastric antrum is the most common site of involvement, but the proximal half of the stomach or even the entire stomach may be involved by this disease.^{35,37} *H. pylori* gastritis is important not only because it may cause upper GI symptoms but also because it is associated with the development of gastric and duodenal ulcers (see Chapter 29), gastric carcinoma (see Chapter 32), and low-grade, B-cell, mucosa-associated lymphoid tissue (MALT) lymphoma (see Chapter 33).

CLINICAL FINDINGS

H. pylori infection is acquired by oral ingestion of the bacterium and is mainly transmitted within families during early childhood.³⁸ *H. pylori* is a worldwide pathogen, being most common in developing countries. In developed countries, *H. pylori* is more common in lower socioeconomic populations.^{35,38} The prevalence of *H. pylori* also increases with age; more than 50% of Americans over 60 years of age are infected by this organism.³⁹ Some people with *H. pylori* may present with dyspepsia, epigastric pain, or other upper GI symptoms,³⁵ but most are asymptomatic.³⁹ Even when symptoms are present, it is often difficult to prove that the symptoms are caused by *H. pylori* because of the high prevalence of this infection.

H. pylori gastritis can be eradicated from the stomach by treatment with a combination of antibiotics and antisecretory agents (proton pump inhibitors).⁴⁰ In a consensus development panel sponsored by the National Institutes of Health in 1994 and a subsequent update conference sponsored by the American Digestive Health Foundation in 1997, combination therapy with antibiotics and antisecretory agents was recommended for all *H. pylori*-positive patients with gastric or duodenal ulcers to accelerate ulcer healing and decrease the rate of ulcer recurrence.^{41,42} However, there are conflicting data about the value of *H. pylori* eradication therapy in patients with non-ulcer dyspepsia.⁴³⁻⁴⁵ As a result, the panels did not recommend treatment for this subset of patients.^{41,42} It therefore remains unclear whether combination therapy should be reserved for patients with *H. pylori* who have gastric or duodenal ulcers or whether patients with *H. pylori* who have nonulcer dyspepsia would also benefit from treatment.

H. pylori gastritis can be accurately diagnosed at endoscopy on the basis of histologic specimens, cultures, and the rapid urease test.^{46,47} However, noninvasive tests for *H. pylori*, such as the urea breath test (using orally administered ¹⁴C- or ¹³C-labeled urea) serologic tests, and stool antigen tests have reported sensitivities and specificities of greater than 90%.^{38,46,47} Highly accurate noninvasive tests are therefore available for detecting this infection.

RADIOGRAPHIC FINDINGS

H. pylori gastritis is the most common cause of thickened folds in the gastric antrum or body on double-contrast barium studies (Fig. 30-9).^{7,48-52} However, other patients may have diffusely thickened folds in the stomach or thickened folds that are confined to the fundus.⁴⁹ Still others with *H. pylori* gastritis may have markedly thickened, lobulated gastric folds (i.e., polypoid gastritis) in a diffuse (Fig. 30-10) or localized (Fig. 30-11) distribution.^{7,49} In such cases, it may be difficult or impossible to differentiate *H. pylori* gastritis from other infiltrative conditions or even malignant tumor involving the stomach (see later, "Differential Diagnosis").

H. pylori gastritis may also be manifested on double-contrast studies by enlarged areae gastricae (≥ 3 mm in diameter) in the stomach (see Fig. 30-9).^{7,49} In the past, enlarged areae gastricae were associated with hypersecretory states and duodenal ulcers.^{53,54} In retrospect, however, this association was probably related to underlying *H. pylori* gastritis in many of these patients. The presence of enlarged areae gastricae should therefore suggest the possibility of *H. pylori*, particularly if associated with thickened gastric folds.^{7,49}

Patients with chronic *H. pylori* gastritis may gradually acquire lymphoid tissue in the gastric mucosa, resulting in the development of intramucosal aggregates of lymphocytes or lymphoid follicles containing germinal centers.^{55,56} This phenomenon is thought to be mediated by a specific immune response to *H. pylori*.⁵⁷ In one study, more than 90% of patients with lymphoid hyperplasia of the stomach were found to have *H. pylori* gastritis.² Lymphoid hyperplasia is therefore a potential marker for *H. pylori* gastritis, even in the absence of other findings. These enlarged lymphoid follicles are manifested on double-contrast barium studies by innumerable tiny

Figure 30-9 *H. pylori* gastritis. **A, B.** In both patients, thickened folds are seen in the body of the stomach and enlarged areae gastricae in the proximal antrum as a result of chronic infection by *H. pylori*. (**A** from Levine MS, Laufer I: *The gastrointestinal tract: Dos and don'ts of digital imaging*. Radiology 207:311-316, 1998.)

Figure 30-10 *H. pylori* causing diffuse polypoid gastritis. **A, B.** Markedly thickened, lobulated folds are seen in the gastric body (**A**) and fundus (**B**). This appearance could be mistaken for severe hypertrophic gastritis, Ménétrier's disease, or lymphoma, but endoscopic biopsy specimens revealed *H. pylori* gastritis without evidence of tumor. (From Sohn J, Levine MS, Furth EE, et al: *Helicobacter pylori* gastritis: Radiographic findings. Radiology 195:763-767, 1995.)

Figure 30-11 *H. pylori* causing localized polypoid gastritis. **A, B.** Focally thickened, lobulated folds are seen in the gastric antrum in **A** and in the gastric body (arrows) in **B**. These findings are worrisome for a localized lymphoma or submucosally infiltrating carcinoma. In both patients, however, endoscopic biopsy specimens revealed *H. pylori* gastritis without evidence of tumor.

Figure 30-12 *H. pylori* gastritis with lymphoid hyperplasia. **A, B.** In both patients, enlarged lymphoid follicles are seen as innumerable tiny, round nodules that carpet the mucosa of the gastric antrum. In **A**, note how many of the nodules have central umbilications with punctate collections of barium seen en face in the lesions. (From Torigian DA, Levine MS, Gill NS, et al: *Lymphoid hyperplasia of the stomach: Radiographic findings in five adult patients. AJR 177:71-75, 2001.*)

(1-3 mm in diameter), round, frequently umbilicated nodules that carpet the mucosa of the gastric antrum or antrum and body (Fig. 30-12).⁵⁸ The radiographic findings are therefore similar to those of lymphoid hyperplasia in the small bowel or colon.

DIFFERENTIAL DIAGNOSIS

The radiographic findings of *H. pylori* gastritis may be indistinguishable from those of hypertrophic gastritis, Ménétrier's disease, or lymphoma when the thickened, lobulated folds have a diffuse distribution,⁵⁹ and the findings may be

Figure 30-13 Low-grade gastric MALT lymphoma. There are multiple round, variably sized, confluent nodules with poorly defined borders in the gastric antrum. These findings are characteristic of gastric MALT lymphoma. In contrast, the nodules of lymphoid hyperplasia have more discrete borders and a more uniform size (see Fig. 30-12). (From Yoo CC, Levine MS, Furth EE, et al: *Gastric mucosa-associated lymphoid tissue lymphoma: Radiographic findings in six patients*. *Radiology* 208:239–243, 1998.)

indistinguishable from malignant tumors such as lymphoma or a submucosally infiltrating carcinoma when the enlarged, polypoid folds have a focal distribution.^{7,49} In other patients with *H. pylori* gastritis, computed tomography (CT) may reveal circumferential thickening of the antrum or focal thickening of the posterior gastric wall, occasionally simulating a gastric carcinoma.⁶⁰ Endoscopy and biopsy are required for a definitive diagnosis when malignant tumor is suspected on the basis of the radiographic findings. Nevertheless, it is important to be aware of the association between *H. pylori* and this polypoid form of gastritis, so careful testing for the organism is performed at the time of endoscopy.

When *H. pylori* gastritis is associated with lymphoid hyperplasia of the stomach, the major consideration in the differential diagnosis is low-grade gastric MALT lymphoma (see Chapter 33). However, gastric MALT lymphoma is manifested on double-contrast studies by multiple round, variably sized, often confluent nodules with poorly defined borders (Fig. 30-13).⁶¹ In contrast, the nodules of gastric lymphoid hyperplasia have more discrete borders, a more uniform size, and, not infrequently, central umbilications (see Fig. 30-12).⁵⁸ Lymphoid hyperplasia of the stomach should also be differentiated from enlarged areae gastricae, another finding associated with *H. pylori* gastritis.^{7,46} However, enlarged areae gastricae have a more polygonal or angulated configuration, producing a sharply margined reticular network (see Fig. 30-9), and they do not contain central umbilications. Other unusual neoplastic lesions such as leukemic infiltrates or even some of the polyposis syndromes may also be manifested on double-contrast studies by multiple small nodules, but the nodules tend to

Figure 30-14 Hypertrophic gastritis. Markedly thickened, lobulated folds are seen in the body of the stomach. The antrum appears normal. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*. 2nd ed. Philadelphia, WB Saunders, 1992.)

have a more variable size and more sporadic distribution. Thus, it is usually possible to differentiate lymphoid hyperplasia in the stomach from other conditions on radiographic criteria. If the findings are equivocal, however, endoscopic biopsy specimens should be obtained for a more definitive diagnosis.

Hypertrophic Gastritis

Hypertrophic gastritis, also known as hypertrophic hypersecretory gastropathy, is characterized by marked glandular hyperplasia and increased secretion of acid in the stomach.^{62,63} Gastric folds may be thickened, not only because of glandular hyperplasia but also because of edema and inflammation. Although the pathogenesis of this condition is uncertain, glandular hyperplasia in the stomach may be caused by pituitary, hypothalamic, or vagal stimuli.⁶² These patients may present with epigastric pain, nausea and vomiting, or, less frequently, signs of upper GI bleeding.^{62,63} If the radiographic or endoscopic findings support the diagnosis of hypertrophic gastritis, treatment with antisecretory agents is usually recommended to suppress acid secretion in the stomach.

RADIOGRAPHIC FINDINGS

Hypertrophic gastritis is manifested on barium studies by thickened folds, predominantly in the gastric fundus and body, because the acid-secreting portion of the stomach is most affected by this condition (Fig. 30-14). Several studies have shown a significant correlation between the degree of fold thickening and the amount of acid secretion in the stomach.^{64,65} The presence of markedly thickened, lobulated folds in the stomach should therefore suggest the possibility of hypertrophic gastritis. In retrospect, however, many if not most cases of previously diagnosed hypertrophic gastritis probably resulted from infection by *H. pylori*, a much more common cause of thickened gastric folds (see earlier, “*Helicobacter pylori* Gastritis”).

DIFFERENTIAL DIAGNOSIS

H. pylori gastritis, Ménétrier's disease, and lymphoma are the major considerations in the differential diagnosis of thickened, lobulated gastric folds. *H. pylori* gastritis can usually be differentiated from hypertrophic gastritis by noninvasive tests for *H. pylori*, such as the urea breath test and serologic tests (see earlier, "*Helicobacter pylori* Gastritis"). Ménétrier's disease should be suspected in patients who have normal or decreased acid secretion and a protein-losing enteropathy (see later, "Ménétrier's Disease"), whereas lymphoma should be suspected when associated findings such as ulcers, masses, or bull's-eye lesions are present in the stomach (see Chapter 33). Gastric carcinoma is a less common cause of thickened folds and is usually associated with loss of distensibility and decreased or absent peristalsis in the involved portion of the stomach.⁶⁶ If the radiographic findings are equivocal, endoscopy and biopsy may be required to rule out malignant tumor. Rarely, other conditions such as Zollinger-Ellison syndrome, eosinophilic gastritis, and varices may be manifested by thickened folds in the stomach, but the correct diagnosis can usually be suggested on the basis of the clinical history and presentation.

Ménétrier's Disease

Since its original description by Ménétrier in 1898, Ménétrier's disease has been recognized as a rare condition of unknown etiology characterized by marked foveolar hyperplasia in the stomach, enlarged gastric rugae, hypochlorhydria, and hypoproteinemia. In the past, this condition was also called cystic gastritis, giant hypertrophic gastritis, giant mucosal hypertrophy, and hyperplastic gastropathy. Ménétrier's disease may cause chronic disabling symptoms, occasionally necessitating gastric resection. Despite its rarity, this entity has received considerable attention in the radiology literature because of its often dramatic appearance on barium studies.

PATHOLOGY

Ménétrier's disease is characterized histologically by thickening and hyperplasia of the mucosa as a result of cystic dilation and elongation of gastric mucous glands associated with deepening of the foveolar pits.⁶⁷ Despite these findings, gastric acid output is decreased or absent in about 75% of cases.⁶⁸ Some patients have a protein-losing enteropathy resulting from loss of protein from the hyperplastic mucosa into the gastric lumen.⁶⁹ Others have varying degrees of gastritis in a patchy or diffuse distribution.

CLINICAL FINDINGS

Ménétrier's disease tends to occur in older patients and is more common in men than in women.⁶⁸ Affected individuals often present with epigastric pain, nausea and vomiting, diarrhea, anorexia, weight loss, and/or peripheral edema.^{68,70} Laboratory studies may reveal hypoalbuminemia resulting from a protein-losing enteropathy, hypochlorhydria resulting from decreased acid secretion, or both. Rarely, the development of gastric carcinoma has been described in patients with preexisting Ménétrier's disease.^{71,72} However, it is unclear whether Ménétrier's disease is a premalignant condition or whether this association is coincidental.

Some patients with Ménétrier's disease have spontaneous remission of symptoms, whereas others respond to treatment with antisecretory agents, vagotomy, or antibiotics. However, most patients have a prolonged illness with intractable symptoms.⁷⁰ A total gastrectomy may be required for patients who are unresponsive to medical therapy.

RADIOGRAPHIC FINDINGS

Ménétrier's disease is typically manifested on barium studies by considerably thickened, lobulated folds in the gastric fundus and body, with relative sparing of the antrum (Fig. 30-15A).^{73,74} In one study, however, the antrum was involved in almost 50% of patients,⁷⁵ so diffuse thickening of gastric folds in no way precludes this diagnosis. The greatest degree of fold thickening usually occurs on or near the greater curvature.⁷³ When the disease is confined to one portion of the stomach, focally enlarged folds may erroneously suggest a polypoid carcinoma (Fig. 30-15B).⁷³

Ménétrier's disease is characterized on CT by a markedly thickened gastric wall, with masslike elevations representing giant, heaped-up folds protruding into the lumen (Fig. 30-15C).⁷⁴ When Ménétrier's disease is suspected on barium studies or CT, full-thickness endoscopic biopsy specimens should be obtained to confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

Although a variety of conditions may be manifested by thickened gastric folds, these conditions rarely produce the degree of fold thickening seen in Ménétrier's disease. When *H. pylori* gastritis is associated with markedly thickened, lobulated folds, the radiographic findings may be indistinguishable from those of Ménétrier's disease.⁴⁶ Gastric lymphoma is sometimes associated with enlarged folds, but neoplastic infiltration should be suggested by the presence of polypoid masses, ulcers, or bull's-eye lesions in these patients (see Chapter 33). Occasionally, gastric carcinoma may be manifested by thickened folds, but infiltrating cancers tend to narrow the lumen, whereas the stomach usually remains pliant and distensible in patients with Ménétrier's disease. Zollinger-Ellison syndrome may also be characterized by thickened folds, but the presence of increased secretions in the stomach or other associated abnormalities (e.g., ulcers, thickened folds) in the duodenum and proximal jejunum should suggest the correct diagnosis (see Chapter 29). Gastric varices should also be included in the differential diagnosis, but varices tend to have a more serpiginous appearance and are usually confined to the region of the gastric cardia or fundus (see Chapter 34). Other conditions involving the stomach, such as Crohn's disease, eosinophilic gastritis, sarcoidosis, tuberculosis, and syphilis, may also be manifested by thickened folds. In these cases, however, the correct diagnosis is usually suggested by the clinical history and presentation.

Atrophic Gastritis

Atrophic gastritis is important because of its association with pernicious anemia, a megaloblastic anemia caused by decreased synthesis of intrinsic factor and subsequent malabsorption of vitamin B₁₂. Pernicious anemia is a disease of older adults; it accounts for 50 of 100,000 hospital admissions in the United States.⁷⁶ Although the pathogenesis of this disease is uncertain,

Figure 30-15 Ménétrier's disease. **A.** Grossly thickened folds are present in the gastric fundus. **B.** In another patient, masslike protrusions of the folds are seen on the greater curvature of the gastric body. This appearance could be mistaken for a polypoid gastric carcinoma. The distal antrum is relatively spared. **C.** In the patient shown in **B**, a CT scan shows massive thickening of the gastric wall with masslike protrusions into the lumen. Endoscopic biopsy specimens in this patient revealed typical pathologic findings of Ménétrier's disease without evidence of tumor. (**A** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

an autoimmune mechanism has been postulated because of the frequent finding of parietal cell or intrinsic factor antibodies in these individuals.⁷⁷

More than 90% of patients with pernicious anemia have underlying atrophic gastritis, characterized pathologically by atrophy of mucosal glands, loss of parietal and chief cells, thinning of the mucosa and, eventually, intestinal metaplasia.⁷⁸ The finding of intestinal metaplasia is particularly worrisome because it is widely believed to be the precursor lesion of the intestinal type of gastric cancer. The literature has also implicated chronic *H. pylori* infection as a major cause of atrophic gastritis, intestinal metaplasia, and gastric carcinoma (see Chapter 32).

PATHOGENESIS

Atrophic gastritis may be classified into two types—type A and type B—which have different histologic, immunologic, and secretory characteristics.^{36,79,80} In type A gastritis, mucosal atrophy is confined to the gastric fundus and body with antral sparing. This type of atrophic gastritis is thought to result from immunologic injury (i.e., antiparietal cell antibodies) and is usually associated with pernicious anemia.⁷⁹

In contrast, type B gastritis is characterized predominantly by antral disease with limited involvement of the fundus and body. This form of atrophic gastritis is more common and usually results from mucosal injury by *H. pylori* or, less

commonly, by other endogenous or exogenous agents such as bile acids or alcohol.^{36,79,80} In patients with *H. pylori*, it has been postulated that the organism progressively damages the gastric mucous layer, causing chronic atrophic gastritis and gastric atrophy.^{34,81} A particular strain of *H. pylori* known as *cagA* (cytotoxin-associated gene A) has been associated with an increased prevalence and degree of atrophic gastritis, predisposing these patients to the development of gastric carcinoma,⁸² so the risk of malignant degeneration may not be the same for all patients with this infection.

CLINICAL FINDINGS

Although atrophic gastritis rarely causes symptoms, some patients with pernicious anemia initially present with neurologic symptoms as a result of long-standing vitamin B₁₂ deficiency. Early diagnosis of pernicious anemia is therefore important, so vitamin B₁₂ replacement therapy can be initiated before the development of irreversible neurologic sequelae. Because the average adult has a 3- to 6-year body store of vitamin B₁₂, the gastric abnormalities in pernicious anemia may predate the hematologic and neurologic abnormalities in this condition by several years. The diagnosis of atrophic gastritis on upper GI studies might therefore permit these patients to be treated with vitamin B₁₂ supplements before the full-blown clinical entity of pernicious anemia has developed.

Relationship to Gastric Carcinoma

Patients with atrophic gastritis and pernicious anemia are at increased risk for the development of gastric carcinoma. In one study, the risk of developing gastric cancer in these patients was found to be about three times greater than that in the general population.⁸³ Although some investigators advocate endoscopic or radiologic surveillance of patients with known pernicious anemia, others believe that the risk of cancer is not high enough to warrant routine screening.⁸⁴⁻⁸⁶ Nevertheless, any patient with pernicious anemia who has occult GI bleeding should be evaluated aggressively to rule out a superimposed gastric carcinoma.

The literature suggests that patients with *H. pylori*-associated atrophic gastritis have a substantially increased risk of developing gastric carcinoma (see Chapter 32). Evidence from several studies has shown that the risk of gastric cancer in *H. pylori*-positive patients is about four times greater than that in patients without this infection.⁸⁷ Because of the high prevalence of *H. pylori* in the population, however, it remains unclear whether widespread eradication of *H. pylori* is justified from a societal perspective to prevent the development of cancer.

RADIOGRAPHIC FINDINGS

The diagnosis of atrophic gastritis may be suggested on single-contrast studies by the presence of a narrowed, tubular stomach with decreased or absent mucosal folds, predominantly in the body and fundus, also known as a bald fundus (Fig. 30-16).⁸⁸ In one study, 80% of patients with atrophic gastritis and pernicious anemia had a fundal diameter of 8 cm or less, absent folds in the fundus and body, and small (1-2 mm in diameter) or absent areae gastricae in the stomach; however, this combination of findings was also present in about 10% of age-matched controls.⁸⁹ The radiologic diagnosis of atrophic gastritis in patients with pernicious anemia has therefore been limited by a lack of criteria that are sensitive and specific for this condition.

When atrophic gastritis is suspected on double-contrast studies, serum vitamin B₁₂ levels should be obtained to determine whether vitamin B₁₂ replacement therapy is indicated.

Many questions remain about the appearance of the areae gastricae in patients with atrophic gastritis. It was previously postulated that variations in the size of the areae gastricae depend on parietal cell mass.⁹⁰ Thus, the small size and frequent absence of areae gastricae in patients with atrophic gastritis may be explained by the loss of parietal cells in these individuals. In contrast, focal enlargement of the areae gastricae should raise the possibility of intestinal metaplasia or even a superficial spreading carcinoma, so this finding should be evaluated by endoscopy and biopsy.

DIFFERENTIAL DIAGNOSIS

Scirrhou carcinoma of the stomach (i.e., linitis plastica) is the most important consideration in the differential diagnosis of atrophic gastritis. However, scirrhou tumors are usually characterized by a nodular, distorted mucosa and thickened, irregular folds,⁹¹ whereas atrophic gastritis is characterized by a smooth, featureless mucosa and decreased or absent folds. Thus, scirrhou carcinomas can almost always be differentiated from atrophic gastritis by radiologic criteria. Scarring from peptic ulcer disease or other conditions may also be characterized by gastric narrowing, but the antrum and body tend to be involved, rather than the fundus.

Granulomatous Conditions

CROHN'S DISEASE

Although Crohn's disease primarily affects the small bowel and colon, early signs of upper GI involvement may be detected on double-contrast barium studies in more than 20% of patients with granulomatous ileocolitis.⁹² Occasionally, the onset of upper GI disease coincides with or even precedes the onset of

Figure 30-16 Atrophic gastritis. A, B. The stomach has a tubular configuration with decreased distensibility, a paucity of mucosal folds, and absence of discernible areae gastricae. These findings are characteristic of atrophic gastritis.

ileal or colonic disease, so these patients do not necessarily have known Crohn's disease when they seek medical attention. Endoscopic biopsy specimens from the stomach or duodenum may fail to reveal granulomas because of the superficial nature of the biopsy specimens and patchy distribution of the disease.⁹³ Thus, the absence of definitive histologic findings should not discourage a diagnosis of gastroduodenal Crohn's disease if the clinical and radiographic findings suggest this condition.

Clinical Findings

Patients with early gastroduodenal involvement by Crohn's disease are often asymptomatic, but those with more advanced disease may present with pain, vomiting, weight loss, or signs of upper GI bleeding.^{94,95} Others may have diarrhea because of associated ileocolic Crohn's disease. The development of a gastroduodenal or duodenocolic fistula is classically manifested by feculent vomiting, diarrhea, and weight loss,⁹⁶ but this triad of findings is present in only about 30% of patients, so gastroduodenal fistulas are not often suspected on clinical grounds.⁹⁷

Asymptomatic patients with early gastroduodenal Crohn's disease require no specific treatment. In patients with more advanced disease, medical treatment for Crohn's disease may relieve epigastric pain or other upper GI complaints.⁹⁴ In contrast, a surgical bypass procedure such as a gastrojejunostomy or duodenojejunostomy may be required to alleviate symptoms of gastric outlet obstruction.⁹⁴

Radiographic Findings

As in the ileum or colon, gastroduodenal Crohn's disease is characterized by nonstenotic and stenotic phases of involvement. The initial nonstenotic phase is manifested by a spectrum of findings, including aphthoid ulcers, larger ulcers, thickened folds, and distorted, effaced or, rarely, cobblestoned mucosa. Subsequent scarring and fibrosis may cause antral, pyloric, or duodenal narrowing with progressive gastric outlet obstruction. Thus, the radiologic features of gastroduodenal Crohn's disease are similar to those in the small bowel and colon.

Gastric Involvement. Gastric Crohn's disease almost always involves the antrum or antrum and body of the stomach.⁹⁸ More proximal extension of Crohn's disease is unusual, and isolated fundal involvement rarely occurs.⁹⁹ When the stomach is affected by Crohn's disease, the duodenum also tends to be involved.^{98,100,101} Most patients have associated granulomatous ileocolitis, but the diagnosis of Crohn's disease may not be known at the time of clinical presentation. When gastric involvement is suggested by upper GI studies, a small bowel follow-through or barium enema should be performed to determine whether there is concomitant ileocolic disease.

Aphthoid ulcers, the earliest histologic lesions of Crohn's disease, are detected in the stomach on double-contrast studies in more than 20% of patients with granulomatous ileocolitis.⁹² These aphthoid ulcers tend to be located in the gastric antrum or in the antrum and body, appearing as punctate or slitlike collections of barium surrounded by radiolucent mounds of edema (Fig. 30-17).^{11,92,102} As a result, these lesions may be indistinguishable from varioliform gastric erosions (see earlier, "Erosive Gastritis").

More advanced gastroduodenal Crohn's disease may be manifested by one or more larger ulcers, thickened folds (Fig. 30-18), or a nodular or cobblestoned mucosa in the gastric antrum or body.^{98,100} Subsequent scarring may lead

Figure 30-17 Early gastric Crohn's disease with aphthoid ulcers. These lesions are indistinguishable from varioliform erosions in the stomach, but the patient had typical findings of Crohn's disease in the terminal ileum. (Courtesy Robert A. Goren, MD, Philadelphia.)

Figure 30-18 Gastric Crohn's disease. Thickened, nodular folds are seen in the antrum of the stomach. (From Levine MS: *Crohn's disease of the upper gastrointestinal tract*. *Radiol Clin North Am* 25:79-91, 1987.)

to the development of a narrowed, tubular, funnel-shaped antrum that has been likened to the appearance of the sacramental ram's horn, or shofar, used to sound the advent of the Jewish New Year (Fig. 30-19).¹⁰³ In other patients, combined gastroduodenal scarring may produce a single, continuous tubular structure involving the antrum and duodenum with obliteration of the normal anatomic landmarks at the pylorus (Fig. 30-20).^{94,100} Because of its resemblance

Figure 30-19 Gastric Crohn's disease with antral narrowing. There is smooth, funnel-shaped narrowing of the antrum, resulting in the classic ram's horn sign of gastric Crohn's disease. (From Levine MS: *Crohn's disease of the upper gastrointestinal tract*. Radiol Clin North Am 25:79–91, 1987.)

Figure 30-20 Gastroduodenal Crohn's disease. There is contiguous narrowing of the antrum and duodenum with obliteration of the normal anatomic landmarks at the pylorus. Because the antrum and duodenum merge together as a single tubular structure, this finding has been described as the pseudo-Billroth I sign of gastroduodenal Crohn's disease. (From Levine MS: *Crohn's disease of the upper gastrointestinal tract*. Radiol Clin North Am 25:79–91, 1987.)

to a postsurgical stomach after a Billroth I partial gastrectomy, this finding has been described as the pseudo-Billroth I sign of gastroduodenal Crohn's disease.¹⁰⁴ Rarely, filiform polyps may be found in the stomach as a sequela of granulomatous gastritis (Fig. 30-21).¹⁰⁵

Figure 30-21 Gastric Crohn's disease with filiform polyps. Multiple linear and ovoid filling defects are seen in the stomach of a patient with long-standing Crohn's disease. (From Levine MS: *Crohn's disease of the upper gastrointestinal tract*. Radiol Clin North Am 25:79–91, 1987.)

Patients with Crohn's disease may occasionally develop gastroduodenal fistulas.^{96,97,106} These individuals usually have underlying Crohn's disease of the transverse colon with extension of a fistula via the gastocolic ligament to the greater curvature of the stomach. On barium studies, the greater curvature may have a nodular or spiculated appearance with thickened, distorted folds in the region of the fistula. These findings probably represent a nonspecific inflammatory response to the adjoining fistula rather than actual extension of Crohn's disease to the stomach. Gastroduodenal fistulas are demonstrated on only about one third of upper GI examinations, so barium enemas are often required for diagnosis of these fistulas.⁹⁷

Although patients with ileocolic Crohn's disease are thought to be at increased risk for developing carcinoma of the small bowel and colon, the relationship between gastric Crohn's disease and gastric carcinoma remains controversial. Anecdotal cases of gastric cancer have been reported in patients with long-standing gastric Crohn's disease,¹⁰⁷ but it is uncertain whether this association is coincidental.

Duodenal Involvement. Although duodenal involvement by Crohn's disease is usually associated with antral involvement, isolated duodenal Crohn's disease occurs more frequently than isolated Crohn's disease of the stomach.¹⁰⁰ As elsewhere in the GI tract, aphthoid ulcers represent the earliest morphologic abnormality on double-contrast studies of the duodenum (Fig. 30-22).^{11,102} With progression, duodenal Crohn's disease may be manifested by thickened, nodular folds (Fig. 30-23), ulcers, or even a cobblestoned appearance because of intersecting linear ulcers similar to those found in advanced ileocolitis.¹⁰⁸

Subsequent scarring may lead to the development of one or more areas of asymmetric duodenal narrowing with outward ballooning or sacculization of the duodenal wall between areas of fibrosis.¹⁰⁸ These strictures typically involve the postbulbar

Figure 30-22 Duodenal Crohn's disease with aphthoid ulcers. Several discrete aphthoid ulcers (arrows) are seen in the distal duodenum near the ligament of Treitz. Note the stellate configuration of the ulcers. (Courtesy Louis Engelhom, MD, Brussels.)

Figure 30-23 Duodenal Crohn's disease with thickened folds. The folds have a thickened, nodular appearance in the proximal duodenum. Peptic duodenitis could produce similar findings.

duodenum, appearing as smooth, tapered areas of narrowing that extend from the apical portion of the duodenal bulb into the descending duodenum (Fig. 30-24).^{104,108} As a result, scarring from duodenal Crohn's disease can usually be differentiated on barium studies from the cloverleaf bulbar deformity associated with scarring from peptic ulcer disease.¹⁰⁴ Other patients may have one or more strictures in the second or third portions of the duodenum that cause marked obstruction and proximal dilation, resulting in a so-called megaduodenum (Fig. 30-25).¹⁰⁸

Primary duodenal Crohn's disease is rarely associated with the development of fistulas. However, duodenocolic fistulas may occasionally result from advanced Crohn's disease

Figure 30-24 Duodenal Crohn's disease with stricture formation. There is smooth, tapered narrowing of the apical portion of the bulb and adjacent segment of the descending duodenum. This appearance is characteristic of Crohn's disease.

Figure 30-25 Duodenal Crohn's disease with a megaduodenum. There is high-grade obstruction (arrow) of the distal duodenum with marked duodenal dilation above this level. (From Levine MS: Crohn's disease of the upper gastrointestinal tract. *Radiol Clin North Am* 25:79-91, 1987.)

Figure 30-26 Crohn's disease with duodenocolic fistulas. Barium enema shows three separate fistulas (arrows) extending from the superior border of the transverse colon to the third and fourth portions of the duodenum. The tubular, severely ulcerated appearance of the transverse colon is secondary to advanced granulomatous colitis. Duodenocolic fistulas almost always result from primary Crohn's disease of the colon with nonspecific inflammatory changes in the duodenum adjoining the fistula. (From Levine MS: *Crohn's disease of the upper gastrointestinal tract*. *Radiol Clin North Am* 25:79-91, 1987.)

involving the transverse colon with subsequent fistulization to the third or fourth portions of the duodenum (Fig. 30-26).^{104,109} Thickened, spiculated folds may be demonstrated in the affected duodenum, but the fistula itself is more likely to be visualized on barium enema than on upper gastrointestinal examination because of the higher pressures generated with this technique. Because these duodenal changes represent a nonspecific inflammatory response rather than actual involvement of the duodenum by Crohn's disease, follow-up barium studies after resection of the fistula may show a completely normal duodenum.¹⁰⁹

Differential Diagnosis

Stomach. Aphthoid ulcers in the stomach may be indistinguishable on double-contrast studies from gastric erosions resulting from NSAIDs or other causes. Although gastric involvement by Crohn's disease is much less common than erosive gastritis, the possibility of Crohn's disease should be suspected when gastric erosions are present in patients with crampy abdominal pain and diarrhea. A small bowel follow-through should therefore be performed to evaluate the terminal ileum in these individuals.

The funnel-shaped antral narrowing associated with more advanced gastroduodenal Crohn's disease must be differentiated from other conditions, particularly a scirrhous gastric carcinoma. In one study, about one third of patients with antral narrowing caused by Crohn's disease underwent surgery because the radiographic findings simulated those of a scirrhous carcinoma.¹⁰³ However, the narrowed antrum of Crohn's disease tends to have a smooth, tubular configuration, whereas

scirrhous carcinoma produces a linitis plastica appearance with a distorted, more irregular mucosal contour.⁹¹ Antral narrowing may also be caused by a variety of other conditions, including scarring from peptic ulcer disease, sarcoidosis, tuberculosis, syphilis, eosinophilic gastritis, caustic ingestion, and radiation. In such cases, the correct diagnosis is often suggested by the clinical history and presentation.

Gastrocolic fistulas may be caused not only by Crohn's disease but also by benign penetrating ulcers on the greater curvature of the stomach in patients who are taking aspirin or other NSAIDs (see Chapter 29).¹¹⁰ Occasionally, these fistulas may also be caused by carcinoma of the stomach or transverse colon invading the gastrocolic ligament.¹⁰⁶ When Crohn's disease is responsible for the fistula, a barium enema examination usually reveals findings of advanced granulomatous colitis in the transverse colon.

Duodenum. Aphthoid ulcers in the duodenum may be indistinguishable on double-contrast studies from varioliform duodenal erosions (see later, "Duodenitis"). However, erosive duodenitis usually involves the duodenal bulb, whereas the aphthoid ulcers of Crohn's disease may be located anywhere in the duodenum from the bulb to the ligament of Treitz. The presence of one or more ulcers in the duodenal bulb or postbulbar duodenum should raise the possibility of Zollinger-Ellison syndrome, but these patients usually have markedly thickened folds and increased secretions in the stomach (see Chapter 29). Thickened, nodular folds in the descending duodenum may be caused not only by Crohn's disease but also by duodenitis, pancreatitis, or other conditions.

Although a smooth segment of tapered narrowing in the postbulbar duodenum is characteristic of the stenotic phase of Crohn's disease, scarring from uncomplicated postbulbar duodenal ulcers may produce a similar appearance.¹¹¹ In contrast, annular duodenal carcinomas can usually be differentiated from benign strictures by their shelflike, overhanging borders. When duodenal involvement by Crohn's disease is suspected on an upper GI examination, a small bowel follow-through or barium enema should be performed to search for associated Crohn's disease in the small bowel or colon.

SARCOIDOSIS

Sarcoidosis is a systemic granulomatous disease of unknown origin, characterized pathologically by the presence of noncaseating granulomas. Most patients have thoracic sarcoidosis, with bilateral hilar lymphadenopathy or fibronodular pulmonary infiltrates on chest radiographs. About 40% of patients have extrathoracic disease involving the eye, skin, lymph nodes, liver, spleen, heart, and musculoskeletal or nervous system. Although sarcoidosis is rarely thought to affect the GI tract, one study found noncaseating granulomas on mucosal biopsy specimens from the stomach in 10% of patients with known sarcoidosis.¹¹² Thus, GI involvement by sarcoidosis may be more common than is generally recognized.

Clinical Findings

Sarcoidosis involves the stomach more frequently than any other portion of the GI tract. Most patients with gastric sarcoidosis are asymptomatic,¹¹² but some may present with nausea, vomiting, bloating, or weight loss because of gastric outlet obstruction.¹¹³ Others may present with epigastric pain or signs

Figure 30-27 Gastric sarcoidosis. **A.** Double-contrast study shows considerable nodularity of the mucosa in the gastric antrum. This patient had pulmonary sarcoidosis, and endoscopic biopsy specimens revealed noncaseating granulomas in the stomach. **B.** In another patient, more advanced gastric sarcoidosis is manifested by marked antral narrowing and deformity. (**B** courtesy Seth N. Glick, MD, Philadelphia.)

of upper GI bleeding resulting from ulceration of the overlying mucosa.¹¹⁴ Treatment with steroids produces a dramatic clinical response in about two thirds of symptomatic patients.¹¹³ Surgical intervention may occasionally be required for patients who have persistent gastric outlet obstruction, massive bleeding, or radiographic or endoscopic findings suggestive of malignant tumor.

Radiographic Findings

Gastric sarcoidosis may be manifested by a spectrum of radiographic findings. In patients with superficial disease, double-contrast studies may reveal a localized area of mucosal nodularity or thickened, irregular folds (Fig. 30-27A).^{115,116} Other patients may have benign- or malignant-appearing ulcers in the stomach.^{114,116} More advanced sarcoidosis may result in smooth, cone-shaped antral narrowing and deformity (Fig. 30-27B).¹¹⁴ Similar findings may be caused by scarring from peptic ulcer disease, caustic ingestion, radiation, and other granulomatous conditions, including Crohn's disease, tuberculosis, and syphilis. Rarely, sarcoidosis may produce more irregular gastric narrowing, mimicking the linitis plastica appearance of an advanced scirrhous carcinoma of the stomach.¹¹⁷ The possibility of gastric sarcoidosis should be suspected, however,

when chest radiographs reveal characteristic findings of sarcoidosis in the thorax.

TUBERCULOSIS

Gastroduodenal involvement occurs in less than 0.5% of all patients with tuberculosis.¹¹⁸ The stomach and duodenum are rarely involved because of the paucity of lymphoid tissue in the upper GI tract, high acidity of peptic secretions, and rapid passage of ingested organisms into the small bowel. Most patients with gastric or duodenal tuberculosis are found to have generalized tuberculosis. Gastroduodenal infection is presumably caused by ingestion of the bacillus or by hematogenous spread to lymphatics in the wall of the stomach or duodenum.¹¹⁹ Although routine pasteurization of milk has dramatically decreased the incidence of GI tuberculosis in the United States, some patients may travel to the United States from other countries such as South Africa or India, where tuberculosis is endemic. Gastric and duodenal tuberculosis have also been encountered in patients with AIDS, particularly those of Haitian origin.¹²⁰

Clinical Findings

Patients with gastroduodenal tuberculosis may present with epigastric pain or signs of upper GI bleeding.¹²¹⁻¹²³ Subsequently, they may develop nausea and vomiting because of progressive scarring and gastric outlet obstruction.¹²³ Although the clinical findings are nonspecific, the possibility of gastroduodenal tuberculosis should be considered in patients who have known pulmonary tuberculosis or who have migrated from areas in which tuberculosis is endemic.

Stool cultures for tuberculosis are unreliable; some patients with pulmonary tuberculosis have positive cultures in the absence of GI infection, whereas others have negative cultures despite GI infection.¹¹⁹ A definitive diagnosis of gastroduodenal tuberculosis can be made when endoscopic biopsy specimens reveal caseating granulomas in the stomach or duodenum, but granulomas may not be found because of their submucosal location and the small size of the specimen samples.¹²³ Depending on the severity of disease, gastroduodenal tuberculosis may be treated by antituberculous drug therapy or, if necessary, gastric resection or bypass.

Radiographic Findings

Gastric tuberculosis may be manifested on barium studies by one or more areas of ulceration, usually on the lesser curvature of the antrum or in the region of the pylorus.^{120,124} Subsequent scarring may cause marked antral narrowing, eventually leading to the development of gastric outlet obstruction.^{124,125} Occasionally, the narrowed antrum may have an irregular contour, simulating the linitis plastica appearance of a primary scirrhous carcinoma of the stomach.¹²⁴ As in the ileocecal region, advanced gastric tuberculosis may be associated with the development of multiple tracks and fistulas.¹²⁴

Duodenal tuberculosis may also be manifested on barium studies by ulcers, thickened folds, narrowing, or fistulas.¹²⁶⁻¹²⁸ As in Crohn's disease, duodenal tuberculosis is often associated with contiguous involvement of the distal antrum. Enlarged tuberculous lymph nodes adjacent to the duodenum may cause widening, narrowing, or obstruction of the duodenal sweep.¹²⁸ Rarely, duodenorenal fistulas may result from spread of tuberculosis from the right kidney to the duodenum.¹²⁹

SYPHILIS

Gastric syphilis is a rare disease, occurring in less than 1% of all patients with secondary or tertiary syphilis.¹³⁰ Nevertheless, gastric involvement should be suspected in young patients with untreated lues who develop epigastric pain, nausea, vomiting, or signs of upper GI bleeding.¹³¹ The diagnosis of gastric syphilis can be confirmed by isolating *Treponema pallidum* on endoscopic biopsy specimens or by demonstrating the typical spirochetes with dark-field microscopy.¹³² Affected individuals usually have a marked clinical response to antiluetic therapy if they are treated before substantial gastric scarring has occurred.

Radiographic Findings

Secondary syphilis involving the stomach is sometimes associated with a severe form of gastritis. In such cases, barium studies may reveal nodules, erosions, shallow or deep ulcers, and thickened folds, predominantly in the antrum (Fig. 30-28).^{130,131,133} In contrast, tertiary syphilis involving the stomach is characterized by progressive scarring and fibrosis, eventually producing a tubular, funnel-shaped antrum.^{130,133} This appearance may be indistinguishable from antral narrowing caused by Crohn's disease, caustic ingestion, radiation, or other granulomatous conditions such as tuberculosis and sarcoidosis. Other patients with tertiary syphilis may have focal narrowing of the gastric body, producing an hourglass- or dumbbell-shaped stomach.¹³³ Rarely, the narrowed stomach may have a more irregular contour, mimicking the linitis plastica appearance of a scirrhous carcinoma of the stomach.¹³⁴ When gastric syphilis is suspected on the basis of the clinical and radiographic findings, endoscopic biopsy specimens are required for a definitive diagnosis.

FUNGAL DISEASES

A variety of fungal diseases may rarely involve the stomach. Gastric histoplasmosis may be manifested by thickened folds, ulceration, or narrowing of the stomach.¹³⁵ Gastric candidiasis may be associated with the development of large aphthoid ulcers or even centrally ulcerated bull's-eye lesions.^{12,136} Other

Figure 30-28 Gastric syphilis. Mucosal nodularity and thickened folds are seen in the antrum in a patient with proven gastric syphilis.

rare fungal infections of the stomach include actinomycosis and mucormycosis.^{137,138}

Other Infections

CYTOMEGALOVIRUS INFECTION

Cytomegalovirus (CMV), a member of the herpesvirus group, is the most common viral pathogen affecting the GI tract in patients with AIDS.¹³⁹ Although the esophagus and colon are more frequent sites of involvement (see Chapters 20 and 58), patients infected with the human immunodeficiency virus (HIV) may occasionally develop CMV gastritis and duodenitis.^{26,140-144} Affected individuals may present with severe abdominal pain or signs of upper GI bleeding.¹⁴³ The treatment of CMV gastritis or duodenitis includes relatively toxic antiviral agents such as ganciclovir, which is associated with bone marrow suppression.¹⁴⁵ Thus, endoscopic biopsy specimens, brushings, or cultures are required for a definitive diagnosis before treating these patients.

Radiographic Findings

CMV gastritis may be manifested on barium studies by mucosal nodularity, erosions, ulcers, thickened folds and, in severe cases, irregular antral narrowing (Fig. 30-29).^{26,140,141} Other opportunistic infections such as cryptosporidiosis and toxoplasmosis may occasionally produce similar findings in patients with AIDS (see later, "Cryptosporidiosis" and "Toxoplasmosis"). Rarely, deep ulcers can result in the development of fistulas to adjacent structures such as the colon.¹⁴² When CMV gastritis is suspected, the diagnosis may be confirmed by demonstrating characteristic inclusion bodies on endoscopic biopsy specimens or brushings or by obtaining positive cultures for CMV.

CMV duodenitis may be manifested on barium studies by luminal narrowing with thickened or effaced folds in the proximal duodenum (Fig. 30-30).^{143,144} The differential diagnosis includes other opportunistic infections in the duodenum in patients with AIDS, such as cryptosporidiosis, strongyloidiasis,

Figure 30-29 Cytomegalovirus gastritis. Mucosal nodularity and tiny ulcerations are seen in the gastric antrum. Note the irregular contour of the stomach. This patient had AIDS.

Figure 30-30 Cytomegalovirus duodenitis. There is marked narrowing and effacement of folds in the proximal descending duodenum and a relatively abrupt transition (arrow) to a normal-appearing duodenum more distally. This patient had AIDS. (From Mong A, Levine MS, Furth EE, et al: Cytomegalovirus duodenitis in an AIDS patient. *AJR* 172:939–940, 1999.)

and tuberculosis. Endoscopic biopsy specimens, brushings, or viral cultures for CMV are therefore required for a definitive diagnosis.

CRYPTOSPORIDIOSIS

Cryptosporidium, a protozoan, may infect the small bowel in patients with AIDS, causing a profuse secretory diarrhea (see Chapter 42). Much less frequently, cryptosporidiosis may involve the stomach; in these cases, barium studies may reveal antral narrowing and rigidity, occasionally associated with one or more deep ulcers.^{140,146,147} CT may also reveal a narrowed antrum with marked thickening of the gastric wall.¹⁴⁸ CMV gastritis should be the major consideration in the differential diagnosis of antral narrowing and ulceration in patients with AIDS (see earlier, “Cytomegalovirus Infection”). When infectious gastritis is suspected on the basis of the radiographic findings, biopsy specimens, brushings, or viral cultures should be obtained from the stomach for a more definitive diagnosis.

TOXOPLASMOSIS

Opportunistic infection of the stomach by toxoplasmosis is a rare cause of antral narrowing on barium studies or of a thickened gastric wall on CT in patients with AIDS.^{149,150} The diagnosis may be confirmed by demonstration of the teardrop-shaped trophozoites in histologic specimens from the stomach.^{149,150} Toxoplasmosis should therefore be included in the differential diagnosis of gastric narrowing or wall thickening in HIV-positive patients.

STRONGYLOIDIASIS

Strongyloides stercoralis is a parasite of worldwide distribution that causes infection of the stomach, duodenum, and proximal small bowel.^{151–153} Cases are occasionally encountered in metropolitan areas of the United States in patients who have emigrated from areas of endemic infection, such as Africa, Asia, and South America.¹⁵³ Strongyloidiasis also occurs as an opportunistic infection in patients with AIDS. Affected individuals may present with abdominal pain, nausea and vomiting, diarrhea, malabsorption, or hypoalbuminemia as a result of a protein-losing enteropathy.¹⁵² A peripheral eosinophilia is present in 25% to 35% of cases.¹⁵²

Radiographic Findings

Gastric involvement by strongyloidiasis may occasionally be manifested on barium studies by antral gastritis or narrowing.^{151,153} However, the duodenum and proximal jejunum are more common sites of involvement. Barium studies may reveal thickened or effaced folds, ulceration, and narrowing or dilation of the affected bowel (Fig. 30-31A).^{151–153} As the disease progresses, there may be tubular narrowing of the lumen and obliteration of the normal fold pattern in the duodenum, producing a classic lead pipe appearance (Fig. 30-31B). Some patients may eventually develop a massively dilated duodenum, or megaduodenum (see Fig. 30-31B). Other conditions associated with a megaduodenum include Zollinger-Ellison syndrome, scleroderma, Crohn's disease, and celiac disease. Scarring of the duodenal wall may occasionally permit reflux of barium into the biliary tree via an incompetent sphincter of Oddi.^{152,153} Although strongyloidiasis is rarely found in the United States, this diagnosis should be considered when barium studies reveal characteristic findings in patients with AIDS or in patients who have a recent history of travel to endemic areas.

Eosinophilic Gastroenteritis

Eosinophilic gastroenteritis is an unusual condition characterized by eosinophilic infiltration of the gastrointestinal tract, primarily the stomach and small bowel.¹⁵⁴ This condition should be differentiated from eosinophilic esophagitis (see Chapter 21). Most patients with eosinophilic gastroenteritis have a peripheral eosinophilia ranging from 10% to 80%,¹⁵⁴ and about 50% of patients have a history of allergic diseases. The clinical symptoms are related to the site and extent of GI disease. Gastric involvement may be manifested by epigastric pain, nausea and vomiting, or, less frequently, signs of upper GI bleeding, whereas small bowel involvement may be manifested by diarrhea, malabsorption, or a protein-losing enteropathy.¹⁵⁴ Some patients have self-limited disease that resolves spontaneously without relapse, but others have chronic relapsing disease, requiring treatment with steroids.^{154,155}

RADIOGRAPHIC FINDINGS

Eosinophilic gastritis usually involves the antrum or antrum and body of the stomach.¹⁵⁶ Rarely, however, disease may be confined to the proximal portion of the stomach with antral sparing.¹⁵⁷ Barium studies may reveal mucosal nodularity, thickened folds, or narrowing and rigidity of the distal half of

Figure 30-31 Duodenal strongyloidiasis. **A.** Markedly thickened, edematous folds are present in the duodenum. This patient had AIDS. **B.** In another patient with more advanced disease, there is a markedly dilated duodenum (a megaduodenum) with obliteration of folds. Also note the smooth, tubular appearance of the proximal jejunum, producing a lead pipe appearance. This patient had recently immigrated to the United States from an area in which strongyloidiasis was endemic. (**B** courtesy Murray K. Dalinka, MD, Philadelphia.)

Figure 30-32 Eosinophilic gastritis. Thickened, nodular folds are seen in the gastric antrum. Other causes of antral gastritis could produce identical findings. (From Herlinger H, Maglinte D [eds]: *Clinical Radiology of the Small Intestine*. Philadelphia, WB Saunders, 1989.)

the stomach (Fig. 30-32).¹⁵⁸ Occasionally, severe antral narrowing may cause gastric outlet obstruction.¹⁵⁹ About 50% of patients with eosinophilic gastritis have concomitant involvement of the small bowel, manifested by diffuse thickening and nodularity of small bowel folds (see Chapter 43).¹⁵⁸

DIFFERENTIAL DIAGNOSIS

When eosinophilic gastritis is manifested by thickened folds, the differential diagnosis includes antral gastritis, *H. pylori* gastritis, hypertrophic gastritis, Ménétrier's disease, Zollinger-Ellison syndrome, lymphoma, and other conditions associated with thickened folds. Despite its rarity, eosinophilic gastritis should be considered in patients who have a peripheral eosinophilia or history of allergic diseases. When eosinophilic gastritis causes antral narrowing, the differential diagnosis includes scirrhous gastric carcinoma, caustic ingestion, radiation, Crohn's disease, and other granulomatous conditions involving the stomach, such as sarcoidosis, tuberculosis, and syphilis. In such cases, the correct diagnosis may be suggested by the clinical history and presentation. When eosinophilic gastritis is suspected on the basis of the upper GI examination, a small bowel follow-through should be performed to determine whether the small bowel is also involved by this disease.

Emphysematous Gastritis

Emphysematous gastritis is a rare type of phlegmonous gastritis in which gas is found in the gastric wall because of infection by gas-forming organisms such as *Escherichia coli*, *Proteus vulgaris*, *Clostridium perfringens*, and *Staphylococcus aureus*.^{160,161} This condition is usually caused by profound insults to the stomach, such as caustic ingestion, gastroduodenal surgery, or gastric volvulus.¹⁶⁰ Subsequent ischemia or necrosis permits gas-forming organisms to enter the gastric wall. Affected individuals may present with an acute fulminating illness characterized by severe abdominal pain, hematemesis, tachycardia, fever, and shock.¹⁶⁰ Supportive therapy with parenteral fluids and antibiotics should be initiated, but a nasogastric tube should not be placed in the stomach because of the high risk of

Figure 30-33 Emphysematous gastritis. Close-up view from an abdominal radiograph shows numerous mottled and bubbly collections of gas in the wall of the stomach. An attempted embolization of a gastric carcinoma led to gastric necrosis and subsequent infection by gas-forming organisms.

perforation. Despite intensive treatment, mortality rates as high as 60% have been reported.¹⁶⁰

RADIOGRAPHIC FINDINGS

Emphysematous gastritis is characterized on abdominal radiographs by multiple streaks, bubbles, or mottled collections of gas in the wall of the stomach, silhouetting the gastric shadow (Fig. 30-33).^{160,161} These intramural gas collections have a constant relationship to the stomach with changes in the patient's position, so they can be differentiated from residue or food, which shifts to the dependent portion of the stomach on upright or decubitus views.¹⁶⁰ Studies with water-soluble contrast agents may confirm the extraluminal location of these gas collections. In other patients, intramural dissection or actual extravasation of contrast medium may be demonstrated. Occasionally, CT may reveal small collections of gas in the gastric wall that are not recognized on abdominal radiographs.¹⁶²

DIFFERENTIAL DIAGNOSIS

Emphysematous gastritis must be differentiated from other rare conditions known as gastric emphysema and gastric pneumatosis. In contrast to emphysematous gastritis, gastric emphysema is characterized by long, linear collections of intramural gas that extend circumferentially around the stomach (see Chapter 34).^{161,163} In gastric emphysema, gas is thought to enter the wall of the stomach via mucosal rents caused by increased

intraluminal pressure associated with gastric outlet obstruction or by iatrogenic trauma resulting from endoscopy or other gastric instrumentation. Despite the dramatic radiographic findings, affected individuals are often asymptomatic. Thus, gastric emphysema can usually be differentiated from emphysematous gastritis on the basis of the clinical and radiographic findings.

Gastric pneumatosis is an extremely rare form of pneumatosis intestinalis in which multiple gas-filled cysts or blebs are found in the wall of the stomach.¹⁶¹ This condition much more commonly involves the small bowel or colon (see Chapter 12). When present in the stomach, the gas-filled intramural cysts may be indistinguishable from the bubbly gas collections associated with emphysematous gastritis. However, patients with gastric pneumatosis are usually asymptomatic, whereas patients with emphysematous gastritis are acutely ill. Thus, these conditions can be differentiated on the basis of the clinical history and presentation.

Caustic Ingestion

Accidental or intentional ingestion of caustic agents may lead to severe injury of the upper GI tract. Although the esophagus is more commonly involved (see Chapter 21), gastroduodenal injury may also occur. The esophagus is typically damaged by strong alkaline agents such as liquid lye (concentrated sodium hydroxide), whereas the stomach and duodenum are more likely to be damaged by strong acids such as hydrochloric, sulfuric, acetic, oxalic, carbolic, and nitric acids. Nevertheless, esophageal injury often occurs in patients who ingest strong acids, and gastroduodenal injury occurs in 5% to 10% of patients who ingest strong alkali.¹⁶⁴ Pathologically, injury to the stomach and duodenum occurs in three phases: (1) an acute necrotic phase 1 to 4 days after caustic ingestion; (2) an ulceration-granulation phase 5 to 28 days after caustic ingestion; and (3) a final phase of cicatrization and scarring 3 to 4 weeks after caustic ingestion.^{164,165}

Patients with gastroduodenal injury by caustic agents may present with severe abdominal pain, nausea, vomiting, hematemesis, fever, and shock.^{165,166} Studies with water-soluble contrast agents are sometimes performed to assess the extent and severity of injury to the upper GI tract. In patients who are stable and have no evidence of perforation, conservative treatment can be initiated with antibiotics, steroids, and parenteral feedings.¹⁶⁶ After a latent period of 3 to 4 weeks, however, many patients develop rapidly progressive gastric outlet obstruction because of antral scarring and fibrosis.¹⁶⁶ As a result, a gastrojejunostomy or partial gastrectomy is sometimes required in these individuals.¹⁶⁵

RADIOGRAPHIC FINDINGS

Ingested caustic agents tend to flow down the lesser curvature of the stomach into the antrum, causing severe pylorospasm that delays emptying into the duodenum.¹⁶⁷ As a result, the lesser curvature and distal antrum of the stomach sustain the greatest degree of damage, whereas the duodenum is relatively spared.¹⁶⁷ During the acute phase of injury, studies with water-soluble contrast agents may reveal thickened folds, ulceration, gastric atony, or mural defects resulting from edema and hemorrhage.¹⁶⁷ In fulminating cases, gastric necrosis may be manifested on abdominal radiographs or CT by streaky, bubbly,

or mottled collections of intramural gas that are unaffected by changes in the patient's position.¹⁶⁸ These intramural collections may result from mechanical disruption of the wall or from secondary infection by gas-forming organisms.¹⁶⁸ In such cases, studies with water-soluble contrast agents may reveal a confined perforation with intramural dissection of contrast medium or loculated perigastric collections (Fig. 30-34). Rarely, these studies may reveal free perforation into

Figure 30-34 Severe gastric injury caused by caustic ingestion. This study with a water-soluble contrast medium shows a grossly abnormal stomach with intramural dissection of contrast medium and numerous mural defects resulting from edema and hemorrhage after acid ingestion.

Figure 30-35 Caustic scarring of the stomach and esophagus.

A. Double-contrast study of the stomach shows marked antral narrowing and deformity as a result of scarring from previous lye ingestion. **B.** Esophagogram shows an associated stricture in the esophagus, extending distally from the carina (arrows) to the gastroesophageal junction. Aspirated barium is also present in both main bronchi. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

the peritoneal cavity. A case of delayed gastric perforation 2 days after ingestion of hydrochloric acid has been reported in which necrosis of the gastric wall was recognized on CT by the absence of the normally enhancing mucosa and remaining gastric wall.¹⁶⁹

If patients survive the acute illness, barium studies performed 4 weeks or more after caustic ingestion may reveal progressive narrowing and deformity of the antrum or antrum and body of the stomach.^{167,170} In some patients, the narrowed antrum may have a smooth, tubular configuration (Fig. 30-35A), whereas in others, it may have a more irregular contour, mimicking the appearance of a primary scirrhous carcinoma of the stomach (Fig. 30-36).^{167,171} Other conditions in the differential diagnosis of antral narrowing include Crohn's disease, sarcoidosis, tuberculosis, syphilis, radiation, and severe scarring from peptic ulcer disease. However, the diagnosis of caustic injury is usually apparent from the clinical history. About 20% of patients with antral scarring from caustic ingestion have associated esophageal scarring (Fig. 30-35B).¹⁷⁰

Because caustic agents cause intense pylorospasm, which has a protective effect on the duodenum, the duodenal bulb and sweep may appear normal in patients with marked antral scarring (see Fig. 30-36). Occasionally, however, duodenal injury may be manifested on barium studies by thickened folds, spasm, ulceration and, eventually, strictures in the duodenum anywhere from the bulb to the ligament of Treitz.¹⁶⁷ These patients almost always have evidence of associated gastric injury.

Radiation

Radiation doses of 50 Gy or more to the upper abdomen may cause substantial injury to the stomach and duodenum when these structures are included in the radiation portal.¹⁷²⁻¹⁷⁴ The distal antrum and pyloric region are usually affected, but the duodenal sweep may also be involved in patients who have

received radiation to the right upper quadrant. Inflammatory changes in the stomach and duodenum typically occur 1 to 6 months after radiation therapy, whereas scarring and fibrosis occur 6 months or more after treatment.^{172,173} Affected individuals may present with dyspepsia, epigastric pain, nausea, vomiting, or signs of upper GI bleeding.^{172,173} Although the symptoms may suggest peptic ulcer disease, the possibility of radiation injury should be considered in any patient who has received radiation therapy to the upper abdomen during the previous 12 months.

RADIOGRAPHIC FINDINGS

The acute phase of radiation injury may be manifested on barium studies by gastroparesis, spasm, thickened folds, or ulceration, predominantly involving the distal gastric antrum and pyloric region and, occasionally, the duodenum.¹⁷²⁻¹⁷⁴ Rarely, perforation of deep ulcers may result in acute peritonitis.¹⁷² Subsequent scarring can lead to the development of antral narrowing 6 months or more after completion of radiation therapy.^{172,174} In such cases, CT may reveal luminal narrowing with nonspecific gastric wall thickening and stranding in the perigastric fat.¹⁷⁴ Rarely, the narrowed antrum may have an irregular contour, simulating a scirrhou carcinoma of the stomach.¹⁷⁵

Floxuridine Toxicity

Because floxuridine (5-FUDR) is taken up almost completely by the liver after infusion into the hepatic artery, it is the agent of choice for hepatic artery infusion chemotherapy in patients with unresectable liver metastases. In the past, 5-FUDR was administered via catheters placed percutaneously into the hepatic artery, but surgically implantable infusion pumps have replaced external catheter systems at many hospitals as the primary means of delivering 5-FUDR into the liver in patients with liver metastases.¹⁷⁶ Although uncommon, gastroduodenal inflammation, ulceration, and bleeding may occur as a direct complication of this form of chemotherapy.

Figure 30-36 Caustic scarring of the stomach. There is asymmetric narrowing and deformity of the distal antrum secondary to scarring from previous acid ingestion. This appearance could be mistaken for a scirrhou carcinoma of the antrum. The duodenum appears normal.

PATHOGENESIS

In patients who are receiving 5-FUDR via percutaneous catheters in the hepatic artery, gastroduodenal toxicity occurs because the drug is infused directly into vessels supplying the stomach and duodenum, such as the gastroduodenal and right gastric arteries. In patients who have hepatic artery infusion pumps, the gastroduodenal and right gastric arteries are surgically ligated at the time of pump placement to prevent overflow of the drug into these vessels. Despite such precautions, gastroduodenal toxicity has been reported as a complication of 5-FUDR therapy via a hepatic artery infusion pump,¹⁷⁷⁻¹⁷⁹ presumably because of the development of small collateral channels between the hepatic artery and gastroduodenal or right gastric arteries after these vessels have been ligated. Whatever the explanation, it is important to recognize that severe gastroduodenal toxicity may occur as a complication of hepatic artery infusion of 5-FUDR, not only via an external catheter system but also via an implantable pump.

CLINICAL FINDINGS

Gastroduodenal toxicity should be suspected when patients who are receiving hepatic artery infusion of 5-FUDR develop intractable nausea, vomiting, epigastric pain, or sign of upper GI bleeding.¹⁷⁹ Although the possibility of metastatic tumor may be considered in these patients, the temporal relationship between 5-FUDR therapy and the onset of symptoms should suggest the correct diagnosis. In most cases, cessation of chemotherapy produces rapid clinical improvement.

RADIOGRAPHIC FINDINGS

Gastroduodenal toxicity resulting from 5-FUDR may be manifested on barium studies by gastroduodenal ulceration or by severe gastritis or duodenitis with markedly thickened, edematous folds in the stomach or duodenum (Fig. 30-37).¹⁷⁹⁻¹⁸²

Figure 30-37 Severe duodenitis caused by 5-floxuridine toxicity. A barium study shows markedly thickened, edematous folds in the duodenum to the level of the ligament of Treitz. This patient was receiving 5-FUDR via a hepatic artery infusion pump. (From Hiehle JF, Levine MS: Gastrointestinal toxicity of 5-FU and 5-FUDR: Radiographic findings. *Can Assoc Radiol J* 42:109-112, 1991.)

Ischemia, bleeding, vasculitis, or other inflammatory or infectious conditions may produce similar findings. However, the temporal relationship between 5-FUDR therapy and the onset of symptoms should suggest the correct diagnosis.

Duodenitis

The pathophysiology of duodenitis is controversial. Because this condition is often associated with gastric hyperacidity, it has been postulated that duodenitis represents part of the spectrum of peptic ulcer disease.¹⁸³⁻¹⁸⁵ However, some patients with duodenitis have normal or even decreased gastric acid secretion, so it may be a distinct clinical entity unrelated to peptic ulcer disease.¹⁸⁶⁻¹⁸⁸ Other data suggest that *H. pylori* may also have a role in the development of this condition.¹⁸⁹

Whatever the pathophysiology, duodenitis is thought to be an important cause of upper GI symptoms, including dyspepsia, epigastric pain, nausea, fatty food intolerance, and early satiety.^{183,184,187,190} Less frequently, erosive duodenitis may be associated with signs of upper GI bleeding, such as hematemesis, melena, and guaiac-positive stool.¹⁸⁷

RADIOGRAPHIC FINDINGS

The diagnosis of duodenitis may be suggested on barium studies in patients who have a spastic, irritable duodenal bulb or thickened, nodular folds in the proximal duodenum (Fig. 30-38).¹⁹¹ For reasons that are unclear, patients with chronic renal failure who are undergoing dialysis often have enlarged duodenal folds to a degree rarely encountered in other patients with duodenitis (Fig. 30-39).^{192,193} However, thickened folds are sometimes present on barium studies in patients in whom there is no endoscopic or histologic evidence of inflammation, so duodenitis has not generally been considered to be a reliable radiologic diagnosis.¹⁹⁴

With double-contrast technique, it is possible to demonstrate more subtle signs of inflammatory disease in the duodenum. This inflammation may be manifested by mucosal

nodules or nodular folds or by diffuse coarsening of the mucosal surface pattern of the bulb, with lucent areas surrounded by barium-filled grooves that resemble the *areae gastricae* in the stomach.¹⁹⁴⁻¹⁹⁶ With double-contrast technique, it also is possible to diagnose erosive duodenitis, a condition previously

Figure 30-39 Severe duodenitis associated with chronic renal failure. Grossly thickened, polypoid folds are seen in the proximal duodenum. This patient was undergoing dialysis for chronic renal failure. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 30-38 Duodenitis. **A.** Thickened, irregular folds are seen in the proximal duodenum. **B.** In another patient, thickened folds and mucosal nodularity are present in the duodenal bulb.

Figure 30-40 Erosive duodenitis. Varioliform erosions are seen in the duodenum as tiny flecks of barium surrounded by radiolucent mounds of edematous mucosa (arrows). (From Levine MS, Rubesin SE, Herlinger H, et al: *Double-contrast upper gastrointestinal examination: technique and interpretation*. Radiology 168:593–602, 1988.)

Figure 30-41 Mucosal pits simulating erosive duodenitis. Punctate collections of barium trapped in tiny epithelial pits can be mistaken for duodenal erosions. However, these collections are not surrounded by radiolucent mounds of edema. (From Bova JG, Kamath V, Tio FO, et al: *The normal mucosal surface pattern of the duodenal bulb: Radiologic-histologic correlation*. AJR 145:735–738, 1985.)

thought to be solely in the domain of the endoscopist.^{6,194,196} These erosions may be found in the duodenal bulb or, less commonly, in the descending duodenum. As in the stomach, incomplete erosions appear as tiny flecks of barium in the duodenum, whereas complete or varioliform erosions appear as central barium collections surrounded by radiolucent halos of edematous mucosa (Fig. 30-40).^{6,194,196} False-positive radiologic diagnoses may occasionally be made because of normal mucosal pits in the duodenum that are mistaken for incomplete erosions on double-contrast studies (Fig. 30-41).¹⁹⁷ Thus, a confident diagnosis of erosive duodenitis can be made only when true varioliform erosions are demonstrated.

Some patients with celiac disease (nontropical sprue) may have severe duodenitis with thickened folds, nodular mucosa, ulcers, or strictures in the descending duodenum.^{198,199} Others may have small (1–4 mm) hexagonal filling defects in the duodenal bulb, producing a distinctive mosaic pattern, or so-called bubbly bulb (Fig. 30-42).²⁰⁰ In contrast to heterotopic gastric mucosa, which predominantly involves the juxtapyloric region of the bulb (see Chapter 31), these nodules tend to be distributed more diffusely throughout the bulb. The presence of a bubbly bulb or thickened duodenal folds should therefore suggest the possibility of celiac disease in patients with malabsorption. A small bowel enema or small bowel biopsy may be required for a definitive diagnosis (see Chapter 43).

Duodenitis may also be caused by Crohn's disease, caustic ingestion, radiation, 5-FUDR toxicity, and infectious processes such as tuberculosis and strongyloidiasis. These conditions and their radiographic findings are discussed elsewhere in this chapter. Finally, duodenitis may occur in patients with underlying pancreatitis involving the head of the pancreas. In such cases, the correct diagnosis is suggested by thickened, spiculated

Figure 30-42 Celiac disease with a bubbly bulb. There are multiple hexagonal filling defects in the duodenal bulb and thickened, irregular folds in the descending duodenum caused by severe duodenitis in a patient with celiac disease. (From Jones B, Bayless TM, Hamilton SR, et al: *"Bubbly" duodenal bulb in celiac disease: Radiologic-pathologic correlation*. AJR 142:119–122, 1984.)

duodenal folds associated with widening of the duodenal sweep or compression of the medial aspect of the descending duodenum (see Chapter 34). When underlying pancreatitis is suspected as the cause of these findings, CT should be performed for a more definitive diagnosis.

Benign Tumors of the Stomach and Duodenum

MARC S. LEVINE

CHAPTER OUTLINE

Mucosal Lesions

Hyperplastic Polyp
Adenomatous Polyp
Duodenal Polyp
Villous Tumor
Polyposis Syndromes

Submucosal Lesions

Gastrointestinal Stromal Tumor
Leiomyoblastoma
Lipoma
Hemangioma
Lymphangioma
Glomus Tumor
Neural Tumor
Granular Cell Tumor
Inflammatory Fibroid Polyp
Ectopic Pancreatic Rest
Brunner Gland Hyperplasia (Brunner Gland Hamartoma)
Duplication Cyst

Between 85% and 90% of all neoplasms in the stomach and duodenum are benign.¹ About 50% are mucosal lesions and 50% are submucosal. Most of these benign neoplasms are discovered fortuitously on radiologic or endoscopic studies performed for other reasons. Occasionally, however, tumors that are large or ulcerated may cause abdominal pain or upper gastrointestinal (GI) bleeding. Depending on their histologic features, some benign tumors are also important because of an associated risk of malignancy. Although gastric and duodenal polyps are rarely diagnosed on single-contrast barium studies, the use of double-contrast technique has led to greater detection of these lesions.

Mucosal Lesions

Gastric polyps comprise about 50% of all benign neoplasms in the stomach.² Polyps are much less common in the duodenum. In the past, gastric polyps were rarely detected on single-contrast barium studies, with a reported incidence of only 0.01% to 0.05%.³ However, the routine use of double-contrast technique has dramatically improved our ability to detect gastric polyps, with a reported incidence of 1% to 2% on double-contrast studies.^{4,5} Most are small, innocuous hyperplastic polyps, but some larger lesions are adenomatous polyps capable of undergoing malignant degeneration via an adenoma-carcinoma sequence similar to that in the colon. The need for endoscopic

biopsy and removal of these polyps is directly related to their size and appearance. Radiologists therefore have an important role in the detection of gastric polyps and in subsequent decisions about patient management.

HYPERPLASTIC POLYP

Hyperplastic polyps are the most common benign epithelial neoplasms in the stomach, comprising 75% to 90% of all gastric polyps.⁶ Because hyperplastic polyps are not premalignant, they must be differentiated from adenomatous polyps, which have a known risk of malignant degeneration. Although histologic specimens are required for a definitive diagnosis, hyperplastic polyps have such a characteristic appearance on double-contrast barium studies that they can usually be differentiated from adenomatous polyps without need for endoscopy.

Pathology

Hyperplastic polyps consist histologically of elongated, branching, cystically dilated glandular structures.^{7,8} They usually appear grossly as small, sessile nodules with a smooth, dome-shaped contour. Because these polyps have a self-limited growth pattern, most are smaller than 1 cm.^{4,8} Hyperplastic polyps almost never undergo malignant degeneration.^{8,9} Nevertheless, affected individuals are at increased risk for harboring separate, coexisting gastric carcinomas. In various series, 8% to 28% of patients with hyperplastic polyps in the stomach have been found to have synchronous gastric carcinomas.^{7,9} This association is probably related to the presence of underlying atrophic gastritis, which predisposes to the development of polyps and cancer.⁸ Hyperplastic polyps are therefore important because of the increased risk of these patients developing gastric carcinoma.

Fundic gland polyps appear to be a variant of hyperplastic polyps arising within fundic gland mucosa in the fundus and body of the stomach.¹⁰ They consist histologically of cystically dilated, hyperplastic fundic glands that have no malignant potential.¹¹ Because affected individuals almost always have multiple (up to 50) gastric polyps, this entity has been called *fundic gland polyposis*.¹¹ Fundic gland polyps are typically found in middle-aged women.¹² Fundic gland polyposis can occur as an isolated condition in the stomach but also develops in about 40% of patients with familial adenomatous polyposis syndrome (FAPS; see Chapter 61).¹³ Thus, colonoscopy is often recommended for patients with fundic gland polyposis to determine whether they have FAPS and whether colonic surveillance is warranted.

Clinical Findings

Most hyperplastic polyps are small (<1 cm in diameter), innocuous lesions detected as incidental findings on radiologic or

endoscopic examinations.⁴ Rarely, polyps that have a friable or ulcerated surface may cause low-grade upper GI bleeding, and pedunculated polyps in the gastric antrum may prolapse through the pylorus, causing intermittent symptoms of gastric outlet obstruction.¹⁴

Radiographic Findings

Most hyperplastic polyps in the stomach appear on double-contrast studies as smooth, sessile, round or ovoid nodules, ranging from 5 to 10 mm in diameter.^{4,8} They tend to occur as multiple lesions in the gastric fundus or body (Fig. 31-1).⁴ When multiple polyps are present, they also tend to be similar in size.⁸

Hyperplastic polyps on the dependent surface of the stomach (i.e., the posterior wall) typically appear on double-contrast studies as smooth, round filling defects in the barium pool, whereas polyps on the nondependent surface (i.e., the anterior wall) appear as ring shadows that are etched in white because of trapping of barium between the edge of the polyp and adjacent mucosa (see Fig. 31-1A). A small hanging droplet of barium, or stalactite, on a nondependent or anterior wall polyp can be mistaken en face for a central area of ulceration (see Fig. 31-1B),¹⁵ but this droplet of barium is seen as a transient finding at fluoroscopy. Occasionally, one or more stalactites may be present as the only sign of hyperplastic polyps on the anterior wall.¹⁶ In such cases, careful examination of the area with prone compression views should demonstrate the underlying polyps responsible for this phenomenon.

Although most hyperplastic polyps are smaller than 1 cm, some atypical polyps can be as large as 2 to 6 cm, appearing as lobulated or pedunculated lesions (Fig. 31-2).^{14,17} A giant

hyperplastic polyp or conglomerate mass of hyperplastic polyps can occasionally be mistaken for a polypoid gastric carcinoma (see Fig. 31-2B).^{14,17} Rarely, pedunculated hyperplastic polyps in the antrum may prolapse through the pylorus into the duodenum, causing gastric outlet obstruction (Fig. 31-3).¹⁴

Fundic gland polyps appear on double-contrast examinations as multiple small (<1 cm in diameter), rounded nodules in the gastric fundus or body that are indistinguishable from hyperplastic polyps (Fig. 31-4).^{11,12,18} In some patients, spontaneous regression of fundic gland polyps has been reported.^{12,13,18}

Differential Diagnosis

Hyperplastic polyps that appear as ring shadows on double-contrast studies must be differentiated from shallow ulcers on the dependent or posterior gastric wall and from unfilled ulcers on the nondependent or anterior wall. With flow technique, however, shallow ulcers on the dependent wall should fill with barium,¹⁹ whereas ulcers on the nondependent wall should fill with barium on prone compression views. Thus, it is usually possible to differentiate these lesions with a biphasic examination, which includes flow technique and prone compression.

Polyps that appear as ring shadows must also be distinguished from see-through artifacts caused by overlying structures that are calcified (e.g., phleboliths) or partially filled with contrast material (e.g., barium-containing colonic diverticula). Such structures can mimic the appearance of anterior wall polyps on a single view (Fig. 31-5A), but their location outside the stomach is readily apparent on images obtained in other projections (Fig. 31-5B).

Hyperplastic polyps that are lobulated or are larger than 1 cm in size cannot be distinguished from adenomatous polyps

Figure 31-1 Multiple hyperplastic polyps. A. Polyps on the dependent surface or posterior wall appear as filling defects in the barium pool (small curved arrows), whereas polyps on the nondependent surface or anterior wall are etched in white (straight arrows). **B.** This patient has multiple anterior wall polyps containing hanging droplets of barium, or stalactites, which could be mistaken for central areas of ulceration. **C.** Innumerable hyperplastic polyps are present in the gastric body. (**B** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 31-2 Atypical hyperplastic polyps. **A.** A long, pedunculated polyp is present in the gastric body. The polyp has a discrete stalk (arrows). This patient had pernicious anemia. **B.** A conglomerate mass of hyperplastic polyps (arrow) is seen in the antrum in another patient. This lesion is quite lobulated and could be mistaken for a polypoid carcinoma.

Figure 31-3 Prolapsed hyperplastic polyp. This patient has a pedunculated polyp (arrow) that has prolapsed from the antrum into the base of the duodenal bulb.

in the stomach. Rarely, giant hyperplastic polyps or a conglomerate mass of hyperplastic polyps can mimic a polypoid gastric carcinoma (see Fig. 31-2B).^{14,17} Thus, polyps that are unusually large or lobulated should be evaluated by endoscopy and biopsy and, if necessary, resected for a definitive diagnosis.

The differential diagnosis for multiple hyperplastic polyps in the stomach includes multiple adenomatous polyps and gastric involvement by one of the polyposis syndromes. However,

Figure 31-4 Fundic gland polyposis. Multiple tiny polyps (arrows) are present in the gastric fundus. These lesions have no malignant potential and are indistinguishable radiographically from hyperplastic polyps.

adenomatous polyps tend to be larger and less numerous and are more lobulated than most hyperplastic polyps. Both types of polyps can occur simultaneously in some patients,¹⁴ but an adenomatous polyp should be suspected if one lesion is disproportionately larger than the others.⁴ A generalized polyposis syndrome should be suspected if multiple polyps are also present in the small bowel or colon (see Chapter 61).

Treatment

Almost all smooth, sessile polyps smaller than 1 cm are hyperplastic polyps that have no malignant potential. Small, round, or ovoid gastric polyps detected on double-contrast studies should therefore be considered innocuous lesions without need for further investigation or treatment. Endoscopic biopsy or polypectomy should be performed, however, if the polyp is lobulated or pedunculated, larger than 1 cm, or enlarges on follow-up barium studies.

Figure 31-5 See-through artifacts mimicking hyperplastic polyps in the stomach. **A.** Multiple ring shadows are seen in the gastric body. These could represent hyperplastic polyps on the anterior wall that are etched in white. **B.** Lateral view shows multiple barium-filled colonic diverticula posterior to the stomach. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

ADENOMATOUS POLYP

Adenomatous polyps constitute less than 20% of all gastric polyps.^{4,5,9} Nevertheless, these polyps are important because they are capable of undergoing malignant degeneration. Thus, they must be treated more aggressively than hyperplastic polyps in the stomach.

Pathology

Adenomatous polyps are composed of dysplastic epithelium. Depending on the predominant glandular architecture, they may be classified as tubular, villous, or tubulovillous adenomas; the vast majority are tubular or mixed tubulovillous adenomas.⁷ Malignant degeneration of these lesions occurs via an adenoma-carcinoma sequence similar to that in the colon. Foci of carcinoma in situ or invasive carcinoma are present in almost 50% of resected adenomatous polyps larger than 2 cm, but malignant changes are rarely found in smaller lesions.^{7,20} As in the colon, the risk of malignant tumor therefore depends primarily on polyp size. Nevertheless, adenocarcinoma is 30 times more common than adenomatous polyps in the stomach, so most gastric cancers are thought to originate de novo and not from preexisting polyps.^{8,9}

Adenomatous polyps are often found in the stomach in patients with chronic atrophic gastritis.^{21,22} Because of the association between atrophic gastritis and gastric carcinoma (see Chapter 32), the risk of developing a separate gastric cancer may be greater than the risk of malignant degeneration in an adenomatous polyp.⁸ As many as 30% to 40% of patients with adenomatous polyps in the stomach have been found to have gastric carcinomas.^{8,9} Thus, detection of an adenomatous polyp in the stomach should lead to a careful search for other lesions.

Clinical Findings

Because of their larger size, adenomatous polyps in the stomach produce symptoms more frequently than hyperplastic polyps. These patients may present with epigastric pain,

bloating, upper GI bleeding or, rarely, symptoms of gastric outlet obstruction.^{23,24}

Radiographic Findings

Most adenomatous polyps diagnosed in the stomach on barium studies are larger than 1 cm.^{5,9,22} They usually occur as solitary lesions, most frequently in the antrum (Fig. 31-6),^{8,20} but multiple adenomatous polyps are sometimes found (Fig. 31-7). The polyps may be sessile or pedunculated, and they tend to be more lobulated than hyperplastic polyps (see Figs. 31-6 and 31-7). When the lesions are pedunculated, the stalk may be seen en face as an inner ring shadow overlying the head of the polyp, producing the Mexican hat sign, which is typically found with pedunculated polyps in the colon (see Fig. 31-6B). Rarely, pedunculated antral polyps may prolapse through the pylorus, causing intermittent gastric outlet obstruction.³

As with hyperplastic polyps, lesions on the nondependent or anterior wall may be etched in white on double-contrast views. Occasionally, a hanging droplet of barium (i.e., stalactite) on these nondependent lesions can mimic the appearance of ulceration.¹⁵ However, adenomatous polyps are rarely ulcerated.

Differential Diagnosis

Adenomatous polyps in the stomach that appear as smooth, sessile lesions may be difficult to distinguish on barium studies from hyperplastic polyps. However, most adenomatous polyps are larger than 1 cm and usually occur as solitary lesions, whereas hyperplastic polyps are almost always smaller than 1 cm and are often multiple.⁴ Adenomatous polyps that are sessile and have a smooth contour can also be mistaken for benign gastrointestinal stromal tumors (GISTs) or other submucosal lesions. Finally, adenomatous polyps that are larger and more lobulated may be indistinguishable from polypoid gastric carcinomas (see Fig. 31-7). Adenomatous polyps often harbor one or more foci of carcinoma in situ or invasive carcinoma, so aggressive management of these lesions is required.

Figure 31-6 Adenomatous polyps. **A.** A sessile polyp (arrow) is present in the antrum. **B.** A pedunculated antral polyp (arrow) is seen in another patient. The stalk appears as an inner ring shadow overlying the head of the polyp, producing the Mexican hat sign. (B courtesy Dean D. Maglinte, MD, Indianapolis.)

Treatment

When a gastric polyp is detected on barium studies, endoscopic biopsy specimens should be obtained if the lesion has features of an adenomatous polyp (i.e., >1 cm, is lobulated or pedunculated, or enlarges on follow-up barium studies). If biopsy specimens confirm the presence of an adenomatous polyp, it should be resected because of the risk of malignant degeneration.²⁵ Regardless of the endoscopic findings, polyps larger than 2 cm should always be resected because of the even greater likelihood that they are adenomatous and the high risk of malignant tumor in adenomatous polyps of this size.^{3,5,9} If invasive carcinoma is present in the resected specimen, a wedge resection of the stomach or partial gastrectomy may be required.²⁶ As in the colon, a much more aggressive approach is therefore warranted in the management of adenomatous

Figure 31-7 Multiple adenomatous polyps. The polyps (arrows) are larger and more lobulated than most hyperplastic polyps in the stomach. The most distal lesion on the greater curvature is indistinguishable from a polypoid carcinoma. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

polyps than hyperplastic polyps because of the increased cancer risk in these patients.

DUODENAL POLYP

Duodenal polyps are much less common than gastric polyps. Hyperplastic polyps, which constitute most gastric polyps, are rarely found in the duodenum. Instead, most duodenal polyps are adenomatous.²⁷ Because these polyps rarely cause symptoms, they are usually detected as incidental findings on radiologic or endoscopic examinations. Occasionally, however, duodenal polyps may cause low-grade upper GI bleeding or obstructive jaundice.²⁸

Radiographic Findings

Duodenal polyps usually appear on barium studies as smooth, sessile lesions in the first or second portion of the duodenum (Fig. 31-8). They tend to be smaller than 2 cm, but giant duodenal polyps have occasionally been described.²⁹ Most duodenal polyps occur as solitary lesions, but multiple adenomatous, hamartomatous, or inflammatory polyps may be found in the duodenum as part of a diffuse polyposis syndrome (see Chapter 61).

Differential Diagnosis

Sessile polyps in the duodenum may be difficult to distinguish on barium studies from benign GISTs, Brunner gland hamartomas, or other submucosal masses, so endoscopy may be

Figure 31-8 Duodenal polyps.

A. Two polyps are present in the duodenal bulb. The lower polyp is seen as a ring shadow (curved arrow) and the higher polyp as a bowler hat (straight arrow).

B. Several adenomatous polyps (arrows) are seen in the descending duodenum in another patient. This study was performed by injecting barium through a tube in the proximal duodenum. (A from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

required for a definitive diagnosis. Occasionally, antral mucosa or even pedunculated antral polyps that prolapse through the pylorus can be mistaken for polypoid lesions in the duodenum (Fig. 31-9; see also Fig. 31-3). However, prolapsed antral mucosa is usually manifested by a characteristic mushroom-shaped defect at the base of the bulb. In other patients, apparent polypoid lesions may result from heaped-up areas of redundant mucosa on the inner aspect of the superior duodenal flexure between the first and second portions of the duodenum (Fig. 31-10). However, these flexural pseudolesions can usually be differentiated from true polyps by their characteristic location and changeable appearance at fluoroscopy.^{30,31}

VILLOUS TUMOR

Adenomatous polyps in the stomach and duodenum that contain predominantly villous elements have been called villous adenomas, papillary adenomas, papillomas, or adenomatous papillomas.³² Because of their high malignant potential, however, the term *villous tumors* is probably best, because it avoids the erroneous impression that these lesions are always benign.^{33,34}

Pathology

Villous tumors in the stomach and duodenum closely resemble those in the colon, appearing grossly as polypoid masses with numerous frondlike projections. They usually occur as solitary lesions, ranging from 3 to 9 cm in size, but giant villous tumors as large as 15 cm have been reported.^{34,35} Villous tumors rarely cause gastric outlet obstruction because of the soft consistency

Figure 31-9 Prolapsed antral mucosa. The prolapsed mucosa produces a mushroom-shaped defect (arrows) at the base of the duodenal bulb. The characteristic appearance and location of prolapsed antral mucosa should differentiate this finding from a true polypoid lesion. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 31-10 Duodenal pseudolesion. Redundant mucosa at the superior duodenal flexure simulates an ulcerated mass (arrows) at the apex of the duodenal bulb. However, the characteristic appearance and location of this finding should suggest a flexural pseudolesion.

of these lesions. They are equally distributed in the stomach, but duodenal lesions tend to be located in the descending duodenum near the papilla of Vater.^{33,35}

Villous tumors in the stomach and duodenum are associated with an even higher risk of malignant change than villous tumors in the colon. The risk of malignant tumor is directly related to the size of the lesion. In the stomach, malignant changes are found in 50% of lesions 2 to 4 cm in size and in 80% of lesions larger than 4 cm. Similarly, malignant changes are found in 30% to 60% of villous tumors in the duodenum, with the highest cancer risk in lesions larger than 4 cm.^{32,33} Although villous tumors in the stomach and duodenum have been classified as benign neoplasms in this chapter, for all practical purposes they should be treated as malignant lesions.

Clinical Findings

Most patients with villous tumors in the stomach and duodenum are over 50 years of age. They may present with signs or symptoms of upper GI bleeding, such as melena, guaiac-positive stool, and iron deficiency anemia.^{33,34} Because villous tumors in the duodenum are often located near the papilla of Vater, some patients may develop obstructive jaundice.^{33,34} In contrast to villous tumors in the colon, however, villous tumors in the stomach and duodenum rarely cause diarrhea or electrolyte depletion.^{33,34} Although gastric and duodenal lesions have the same secretory capabilities as those in the colon, reabsorption of fluid and electrolytes in the small and large bowel apparently prevents the development of a diarrheal syndrome.

Villous tumors in the stomach and duodenum should be resected because of the high risk of malignant degeneration.

Figure 31-11 Villous tumor in the stomach. A giant villous tumor (arrows) in the gastric antrum has a characteristic soap bubble appearance because of trapping of barium between the frondlike projections of the tumor. This lesion could be mistaken for a bezoar but, in contrast to bezoars, it did not move with changes in the patient's position. (Courtesy Abraham Ghiatis, MD, San Antonio, TX.)

Some benign lesions can be removed by endoscopy, but those harboring invasive cancer usually require surgery.^{32,33,35}

Radiographic Findings

Villous tumors in the stomach and duodenum usually appear on barium studies as polypoid masses, ranging from 2 to 9 cm in size.³⁴⁻³⁶ The lesions often have a reticular or soap bubble appearance with serrated, feathery margins caused by trapping of barium in multiple clefts between the frondlike projections of the tumor (Figs. 31-11 and 31-12).^{30,36,37} Thus, villous tumors in the stomach and duodenum have the same radiographic features as those in the colon.

Villous tumors in the duodenum tend to be located near the papilla of Vater (see Fig. 31-12),³³⁻³⁵ but occasionally are found as far proximally as the duodenal bulb.³⁸ Because these lesions are easily obscured by superimposed mucosal folds, they are best visualized on double-contrast studies with optimal distention of the duodenum. Hypotonic duodenography (after intravenous [IV] administration of 1 mg of glucagon) is a particularly effective technique for effacing the overlying folds, so subtle lesions in the peripapillary duodenum are better seen (see Fig. 31-12B).^{35,37}

Differential Diagnosis

A large gastric bezoar may occasionally produce a soap bubble appearance, mimicking that of a villous tumor in the stomach

Figure 31-12 Villous tumors in the duodenum. **A.** This villous tumor appears as a polypoid mass (arrows) just below the level of the papilla. Note the characteristic reticular surface of the lesion. **B.** In another patient, a more subtle villous tumor (arrows) is seen with optimal distention of the descending duodenum. Again, note the reticular surface of the lesion. (A from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

as a result of barium trapped in the interstices of the bezoar. However, the freely mobile nature of the bezoar with changes in the patient's position should suggest the correct diagnosis. Carcinoma or lymphoma of the stomach or duodenum may also be manifested by a bulky intraluminal mass, but these lesions rarely produce a soap bubble appearance.

POLYPOSIS SYNDROMES

With the widespread use of double-contrast radiography and endoscopy, gastroduodenal involvement by the polyposis syndromes has proved to be far more common than previously recognized (see Chapter 61). In patients with FAPS, detection of adenomatous polyps in the stomach or duodenum is particularly important because of the malignant potential of these lesions and the increased risk of developing gastric or duodenal carcinoma. Some investigators therefore believe that periodic surveillance of the upper GI tract should be performed on all patients with FAPS. Other polyposis syndromes involving the stomach and duodenum include Peutz-Jeghers syndrome, Cronkhite-Canada syndrome, juvenile polyposis, and Cowden's disease (see Chapter 61). In patients with Cronkhite-Canada syndrome, barium studies may reveal distinctive whiskering along the margins of the stomach because of trapping of barium between tiny mucosal excrescences (Fig. 31-13).³⁹ When accompanied by characteristic ectodermal findings, this appearance should be highly suggestive of Cronkhite-Canada syndrome.

Submucosal Lesions

The terms *submucosal* and *intramural* are used interchangeably in this chapter. Nevertheless, it should be recognized that all submucosal lesions are intramural, but not all intramural

Figure 31-13 Cronkhite-Canada syndrome involving the stomach. A single-contrast view shows whiskering (arrows) of the greater curvature because of trapping of barium between tiny mucosal excrescences. This finding is characteristic of gastric involvement by Cronkhite-Canada syndrome.

lesions are submucosal because they can also arise from the muscularis propria or even the subserosa. These mesenchymal lesions constitute about 50% of all benign neoplasms in the stomach or duodenum.² Almost 90% are GISTs.⁴⁰ Other submucosal lesions include leiomyoblastomas, lipomas, hemangiomas, lymphangiomas, glomus tumors, neural tumors, granular cell tumors, inflammatory fibroid polyps, ectopic pancreatic

rests, Brunner gland hamartomas, and duplication cysts. Most benign submucosal tumors are discovered as incidental findings at surgery or autopsy, but lesions that are large or ulcerated may cause abdominal pain or upper GI bleeding. Some mesenchymal tumors are important because of an increased risk of malignancy. Submucosal masses may be difficult to visualize at endoscopy because the overlying mucosa appears normal. As a result, barium studies are particularly helpful for detecting these lesions.

GASTROINTESTINAL STROMAL TUMOR

Although GISTs were once thought to represent smooth muscle tumors (leiomyomas and leiomyosarcomas), they are now believed to arise from the interstitial cells of Cajal and are characterized by their unique immunohistochemical expression of CD-117, also known as c-kit, a cell surface membrane receptor with tyrosine kinase activity.^{41,42} In one study, almost all submucosal masses previously classified as smooth muscle tumors were found to be GISTs, with the exception of submucosal masses in the esophagus, in which true leiomyomas were far more common.⁴² GISTs constitute about 90% of mesenchymal tumors and 40% of all benign tumors in the stomach and duodenum.^{1,40,43} These lesions are important, not only because they may cause symptoms, but also because a small percentage are found to be malignant.

Pathology

GISTs consist histologically of intersecting bundles of spindle-shaped cells in a characteristic whorling pattern that distinguishes these tumors from normal smooth muscle.^{40,44} Depending on their growth pattern, GISTs may appear grossly as endogastric, exogastric, or so-called dumbbell lesions.¹ About 80% are endogastric lesions that remain intramural but grow toward the lumen. Another 15% are exogastric lesions that grow outward from the stomach toward the peritoneal cavity. The remaining 5% are dumbbell-shaped lesions that have endogastric and exogastric components.

Almost all benign gastric and duodenal GISTs occur as solitary lesions, but multiple tumors are found in 1% to 2% of patients.¹ Most benign GISTs in the stomach and duodenum are smaller than 3 cm, but some patients may have giant lesions as large as 25 cm.⁴⁴ As these tumors enlarge, they often outgrow their blood supply, causing central necrosis and ulceration.⁴⁵ In various series, ulceration has been documented in 50% to 70% of all gastric GISTs larger than 2 cm.^{1,45}

About 90% of GISTs in the stomach are found to be benign lesions.¹ However, it is often difficult to differentiate benign from malignant GISTs by histopathologic criteria.^{46,47} The most commonly accepted microscopic index of malignancy is the degree of mitotic activity in the tumor.⁴⁴ Nevertheless, mitotic activity may be increased in only a portion of a malignant GIST, so random biopsy specimens or frozen sections may erroneously suggest a benign lesion. Thus, a definitive diagnosis of malignant tumor ultimately depends on the tumor's biologic behavior and the demonstration of invasive growth beyond the stomach via direct extension, lymphatic spread, or hematogenous metastases (see Chapter 33).⁴³

Clinical Findings

Benign gastric and duodenal GISTs occur with about equal frequency in men and women. Affected individuals are usually

over 50 years of age.⁴⁴ Most patients with lesions smaller than 3 cm are asymptomatic. As these tumors enlarge, ulceration of the lesion may cause epigastric pain or upper GI bleeding, manifested by hematemesis, melena, guaiac-positive stool, or iron deficiency anemia.^{43,44} Occasionally, pedunculated GISTs in the gastric antrum may cause nausea and vomiting because of intermittent gastric outlet obstruction.^{48,49}

Radiographic Findings

Most benign GISTs are not diagnosed on abdominal radiographs, but a large tumor in the stomach can occasionally be recognized as a soft tissue mass indenting the gastric air shadow.² Rarely, benign GISTs in the stomach contain irregular streaks or clumps of mottled calcification that are visible on abdominal radiographs, barium studies, or computed tomography (CT) (Fig. 31-14).^{50,51} Mucinous adenocarcinomas of the stomach may also calcify, but the calcification in these lesions tends to have a punctate, granular, or finely stippled appearance (see Chapter 32).⁵² The differential diagnosis for left upper quadrant calcification also includes calcified adrenal, renal, or splenic lesions.

Benign GISTs typically appear on barium studies as discrete submucosal masses (Figs. 31-15 and 31-16). These tumors have the same radiographic features as intramural, extramucosal lesions elsewhere in the GI tract. When viewed in profile, the lesions have a smooth surface that is etched in white on double-contrast images, and their borders form right angles or slightly obtuse angles with the adjacent gastric or duodenal wall (see Fig. 31-15A). When viewed en face, the intraluminal surface of these tumors has abrupt, well-defined borders (see Fig. 31-15B). Because the overlying mucosa is usually intact, a normal *areae gastricae* pattern can sometimes be seen overlying these lesions.

Gastric GISTs vary in size from tiny lesions of several millimeters to enormous masses that encroach substantially on the lumen.⁴⁴ Tumors larger than 2 cm frequently contain areas of ulceration, manifested by a central barium-filled crater within the surrounding submucosal mass (see Fig. 31-16A). Because of their characteristic appearance, centrally ulcerated GISTs viewed en face have been described as bull's-eye or target lesions. Occasionally, a hanging droplet of barium (i.e., stalactite) on an anterior wall GIST can mimic the appearance of ulceration (see Fig. 31-15B), but the stalactite can usually be recognized as a transient finding at fluoroscopy.¹⁵

Because ulcerated GISTs may cause major upper GI bleeding, ulceration is generally considered an indication for surgery. Rarely, however, complete healing of ulceration in benign gastric GISTs can occur in patients treated conservatively with antisecretory agents (see Fig. 31-16B), so medical treatment may lead to cessation of bleeding when surgery is contraindicated.⁵³ If necessary, bleeding can also be controlled angiographically by selective embolization of feeding vessels.⁵⁴

Although most benign GISTs in the stomach have a typical submucosal appearance, exogastric tumors that grow outward from the stomach may be difficult to differentiate from extrinsic mass lesions. However, the presence of a central dimple or spicule at the apex of the mass should suggest an intramural rather than an extrinsic lesion.⁵⁵ This area of tenting probably results from traction on the gastric wall by the base or pedicle of the mass as it enlarges. Other GISTs that grow intraluminally may develop pseudopedicles. Rarely, pedunculated antral GISTs may prolapse into the duodenum or act as the lead

Figure 31-14 Benign GISTs with calcification. **A.** Close-up view of an abdominal radiograph reveals a dense clump of calcification (arrow) in the left upper quadrant. **B.** Barium study shows that this calcification (black arrow) is located within a discrete submucosal mass (white arrows) in the stomach. At surgery, the lesion was found to be a benign GIST. **C.** In another patient, a peripherally calcified benign gastric GIST (arrow) is shown on a CT scan. (C courtesy Alec J. Megibow, MD, New York.)

Figure 31-15 Benign GISTs. **A.** A submucosal mass is seen in profile in the gastric fundus. The lesion has smooth borders that form slightly obtuse angles with the adjacent gastric wall. This view was taken with the patient upright, and a barium stalactite (arrow) is seen hanging down from the inferior surface of the lesion. **B.** In another patient, a small GIST is seen en face (arrow) in the gastric body. This lesion also has typical features of a submucosal mass with smooth, well-defined borders. A hanging droplet of barium or stalactite is visible on the surface of this anterior wall lesion. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

point for a gastrogastic or gastroduodenal intussusception (Fig. 31-17).^{48,49}

Differential Diagnosis

GISTs are the most common benign submucosal tumors in the stomach and duodenum. However, other intramural lesions

may also be manifested by discrete submucosal masses. Occasionally, lipomas may be recognized by their tendency to change in size and shape at fluoroscopy (see later, “**Lipoma**”), whereas ectopic pancreatic rests may be suggested by their characteristic location on the greater curvature of the distal antrum (see later, “**Ectopic Pancreatic Rest**”). In most cases, however, these

Figure 31-16 Ulcerated GIST with complete healing of the ulcer. **A.** Initial study reveals a relatively large benign GIST (arrows) in the fundus with a central area of ulceration, producing a bull's-eye lesion. **B.** Follow-up study 3 years later shows complete healing of the ulcer within the tumor (arrows). (From O'Riordan D, Levine MS, Yeager BA: Complete healing of ulceration within a gastric leiomyoma. *Gastrointest Radiol* 10:47-49, 1985.)

Figure 31-17 Benign GIST with gastroduodenal intussusception. **A.** A large, smooth mass extends from the duodenal bulb into the descending duodenum. Note the characteristic coiled spring appearance of an intussusception and foreshortening of the distal antrum. This patient had a benign GIST in the stomach that prolapsed through the pylorus, acting as the lead point for this gastroduodenal intussusception. **B.** CT scan shows the target sign of an intussusception with concentric rings (arrows) in the descending duodenum.

submucosal lesions cannot be differentiated by radiologic criteria.

Centrally ulcerated GISTs that are viewed en face appear as typical bull's-eye or target lesions. Although a solitary bull's-eye lesion in the stomach or duodenum is most likely to represent an ulcerated GIST on empiric grounds, other benign mesenchymal tumors that are ulcerated can produce identical findings. In contrast, the presence of multiple bull's-eye lesions should suggest a malignant tumor such as metastatic disease or lymphoma because GISTs in the stomach or duodenum are rarely multiple.¹

An antral or duodenal ulcer surrounded by a radiolucent mound of edema may simulate an ulcerated GIST. Conversely, an ulcerated GIST may erroneously suggest an ulcer in the stomach or duodenum. However, a benign GIST usually has discrete borders, whereas the edematous mound surrounding a gastric or duodenal ulcer tends to have a more gradual transition.

Exogastric GISTs are often difficult to distinguish on barium studies from extrinsic masses involving the stomach, particularly pancreatic pseudocysts or other pancreatic lesions compressing the stomach. Gastric compression by an enlarged liver, spleen, kidney, or other abdominal mass may produce similar findings. As noted, however, the presence of a central dimple or spicule at the apex of the mass should suggest an exogastric intramural lesion such as a GIST.⁵⁵ When extrinsic mass lesions are suspected, ultrasound, CT, and magnetic resonance imaging (MRI) may be helpful for establishing the correct diagnosis.

Treatment

Small, asymptomatic submucosal masses detected in the stomach or duodenum on barium studies can probably be followed conservatively without need for endoscopic or surgical intervention, because most of these lesions are found to be benign GISTs. In such cases, follow-up barium studies or endoscopy may be performed at yearly intervals to be certain that the

tumor is not enlarging. However, ulcerated lesions or lesions larger than 2 cm should probably be resected because of the increased risk of malignancy and the difficulty distinguishing benign and malignant GISTs by histopathologic criteria.^{1,41,43} Depending on the size of the lesion, it can be enucleated, locally excised or, if necessary, removed by partial gastrectomy or duodenectomy.^{43,44} Patients who have more worrisome lesions may benefit from adjuvant therapy with imatinib (Gleevec), a tyrosine kinase inhibitor, to decrease the risk of developing recurrent tumor.⁵⁶

LEIOMYOBLASTOMA

Leiomyoblastomas are unusual smooth muscle tumors that occur predominantly in the stomach. However, these tumors have also been reported in the small bowel, retroperitoneum, and uterus.⁵⁷ Leiomyoblastomas differ histologically from GISTs, but the gross morphologic findings are almost identical.⁴⁴ As with GISTs, leiomyoblastomas are important because of the risk of malignancy in these lesions.

Pathology

Leiomyoblastomas consist histologically of round, polygonal, or epithelioid cells with eccentric nuclei, perinuclear vacuolization, and a clear or acidophilic cytoplasm.⁵⁷⁻⁵⁹ Because of the histologic findings, these tumors have also been called *epithelioid leiomyomas*.^{58,59} Most leiomyoblastomas are benign lesions, but metastases to the liver or other structures occur in about 10% of patients.⁶⁰ As with GISTs, malignant lesions usually have increased mitotic activity on microscopic examination.⁵⁸ Size is also an important factor in predicting biologic behavior because metastases rarely occur with lesions smaller than 6 cm.⁵⁸ Nevertheless, some authors believe that all leiomyoblastomas should be resected because of the difficulty in distinguishing benign and malignant lesions by histopathologic criteria.^{57,59}

Leiomyoblastomas tend to occur as solitary lesions in the stomach, usually in the antrum, but multiple tumors have been reported.^{58,61} As with GISTs, most lesions appear as submucosal masses, often with central necrosis and ulceration.^{60,61} Occasionally, they may have an exogastric pattern of growth.⁶¹

Clinical Findings

In contrast to leiomyomas, leiomyoblastomas are more common in men than in women.^{60,61} These patients may be asymptomatic or may present with pain, vomiting, upper GI bleeding, or

a palpable abdominal mass.^{57,60,61} Rarely, giant exogastric leiomyoblastomas may rupture suddenly into the peritoneal cavity, causing catastrophic intraperitoneal bleeding.⁶²

Radiographic Findings

Gastric leiomyoblastomas are indistinguishable on barium studies from GISTs (see earlier, “Gastrointestinal Stromal Tumor”). Most appear as smooth submucosal masses, often containing central areas of ulceration (Fig. 31-18).⁶¹ Some endogastric lesions can become pedunculated, whereas exogastric lesions can be mistaken for extrinsic masses involving the stomach (Fig. 31-19A).⁶¹ Cystic degeneration of these exogastric

Figure 31-18 Gastric leiomyoblastoma. A large submucosal mass is present in the gastric body. This lesion is indistinguishable from a benign GIST.

Figure 31-19 Exogastric leiomyoblastoma. **A.** Barium study shows a smooth extrinsic impression (arrows) on the lesser curvature of the gastric body. **B.** CT scan shows a smooth, well-defined cystic mass (arrow) abutting the stomach. At surgery, this patient was found to have an exogastric leiomyoblastoma with cystic degeneration of the tumor. (Courtesy Kyunghee C. Cho, MD, Newark, NJ.)

leiomyoblastomas is occasionally manifested on CT by a cystic mass abutting the stomach (see Fig. 31-19B).^{63,64} Rarely, CT may show areas of calcification within the tumor.⁶⁴ The differential diagnosis for these lesions is discussed in detail in the previous section on GISTs.

LIPOMA

Gastric lipomas are rare tumors, accounting for only about 5% of GI tract lipomas and less than 1% of all gastric neoplasms.⁶⁵ Duodenal lipomas are even rarer. Most of these lesions are detected as incidental findings on barium study, endoscopy, or autopsy. Thus far, no cases of malignant degeneration of GI lipomas have been reported. Occasionally, however, lesions that are large or ulcerated may cause obstruction or bleeding. Although lipomas are difficult to differentiate on barium studies from other submucosal masses in the stomach or duodenum, CT has proved to be a valuable technique for diagnosing these lesions.

Pathology

Lipomas are composed of mature fat cells surrounded by a fibrous capsule. They tend to occur as solitary lesions, usually in the gastric antrum.⁶⁶⁻⁶⁸ About 95% are endogastric lesions

that arise in the submucosa and grow toward the lumen, whereas the remaining 5% are exogastric lesions that arise in the subserosa and grow outward from the stomach.⁶⁶ As lipomas enlarge, they may develop central ulcers caused by pressure necrosis of the overlying mucosa.⁶⁷

Clinical Findings

Small lipomas usually cause no symptoms, but larger lesions may undergo ulceration, causing abdominal pain or upper GI bleeding.^{66,67,69} Rarely, pedunculated antral lipomas that prolapse through the pylorus may cause intermittent gastric outlet obstruction with recurrent nausea and vomiting.⁶⁶ Small lipomas in asymptomatic patients can be followed without need for surgery. However, larger lesions that cause symptoms should be resected.⁶⁷

Radiographic Findings

Barium studies typically reveal a smooth submucosal mass or centrally ulcerated bull's-eye lesion indistinguishable from a benign GIST or other mesenchymal tumor (Fig. 31-20A).⁶⁸ Most gastric lipomas occur as isolated lesions in the antrum,⁶⁶⁻⁶⁸ but multiple lipomas are occasionally present in the stomach or duodenum.⁷⁰ Because lipomas have a soft consistency, the correct diagnosis can be suggested if the lesions change in size

Figure 31-20 Gastric lipoma. **A.** Double-contrast view shows a smooth submucosal mass (arrow) in the antrum. **B.** Prone single-contrast views show how the lesion changes in size and shape with varying degrees of compression. This changing appearance should be highly suggestive of a lipoma. **C.** CT scan shows how the lesion in the antrum (cursor 2) has the same density as perirenal fat (cursor 1), confirming the presence of a lipoma. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

and shape at fluoroscopy (Fig. 31-20B).⁷⁰ Rarely, pedunculated antral lipomas may prolapse through the pylorus into the duodenum, acting as the lead point for a gastroduodenal intussusception.⁶⁸

CT has proved to be of considerable value for diagnosing GI lipomas.⁷¹⁻⁷⁵ These lesions typically appear on CT as well-circumscribed lesions of uniform fatty density with an attenuation of 70 to 120 HU (Fig. 31-20C).^{71,74} Occasionally, CT may reveal linear strands of soft tissue density or ulceration within the tumor.^{68,74} It should therefore be recognized that these findings can occur in a benign lipoma and are not signs of a liposarcoma, which is extremely rare in the GI tract. When a gastric or duodenal lipoma is definitively diagnosed by CT, unnecessary endoscopy or surgery can be avoided.

HEMANGIOMA

Hemangiomas constitute less than 2% of all benign tumors in the stomach. They are even rarer in the duodenum. The lesions may be classified as capillary hemangiomas composed of numerous tiny vascular structures or, less commonly, as cavernous hemangiomas composed of large blood spaces or sinusoids lined by endothelial tissue. It is uncertain whether these lesions are congenital malformations or true neoplasms capable of autonomous growth. They tend to occur as solitary lesions, but multiple hemangiomas may be present in the stomach, small bowel, and colon in patients with hemangiomatosis. Occasionally, GI hemangiomas are associated with telangiectasia of the skin.⁷⁶

Although sarcomatous changes are rarely found in GI hemangiomas, these highly vascular lesions are dangerous because of the risk of massive upper GI bleeding. Endoscopy typically reveals a bluish black submucosal lesion. Surgical resection is usually curative.

Radiographic Findings

Hemangiomas in the stomach typically appear on barium studies as smooth submucosal masses indistinguishable from GISTs or other mesenchymal tumors.⁷⁶ However, the presence of phleboliths within the lesion should be virtually pathognomonic of a hemangioma.⁷⁷ Such phleboliths are occasionally visible on abdominal radiographs, and their intimate relationship to the stomach may be confirmed on barium studies or CT.⁷⁷ The presence of other hemangiomas on the skin should also suggest the correct diagnosis.

LYMPHANGIOMA

Lymphangiomas are rare benign tumors of the stomach and duodenum.⁷⁸ These lesions consist histologically of irregularly dilated lymphatic channels lined by benign-appearing endothelial cells. Lymphangiomas are thought to be developmental malformations arising from sequestered lymphatic tissue.⁷⁸ They often have a cystic appearance because of progressive accumulation of fluid.

Although they may occur anywhere in the body, lymphangiomas rarely affect the GI tract. These lesions are usually detected as incidental findings in asymptomatic patients. Occasionally, however, they are large enough to cause obstruction or intussusception.⁷⁸ Gastric or duodenal lymphangiomas that cause symptoms should be resected.

Radiographic Findings

Lymphangiomas may appear on barium studies as smooth intramural masses indistinguishable from benign GISTs or other mesenchymal tumors in the stomach and duodenum.⁷⁸ Because of their cystic nature, these lesions may be pliable at fluoroscopy and are occasionally seen to change in shape with manual compression.⁷⁸ However, gastric and duodenal lipomas may produce identical findings.

GLOMUS TUMOR

Glomus tumors are derived from glomus bodies, specialized arteriovenous communications that regulate temperature in the skin.⁷⁹ Because glomus bodies are particularly abundant in the nail beds and pads of the finger tips and toes, glomus tumors are typically subungual in location. Rarely, glomus tumors are found in the stomach.⁷⁹⁻⁸¹

Most patients with glomus tumors in the stomach are asymptomatic. However, ulcerated tumors may cause upper GI bleeding.^{79,81} Local excision is usually curative, but these highly cellular lesions can appear malignant on frozen sections at the time of surgery, so an unnecessarily extensive resection is sometimes performed.^{79,80}

Radiographic Findings

Glomus tumors in the stomach usually occur as solitary lesions in the antrum, ranging from 1 to 4 cm in size.⁸⁰ These tumors appear on barium studies as smooth submucosal masses (with or without ulceration) that are indistinguishable from benign GISTs or other more common mesenchymal tumors in the stomach (Fig. 31-21).⁸² Occasionally, glomus

Figure 31-21 Glomus tumor. An ulcerated submucosal mass (arrows) is seen on the greater curvature of the antrum. This lesion cannot be distinguished from other more common mesenchymal tumors in the stomach. (Courtesy Bruce Knox, MD, Norfolk, VA.)

tumors contain tiny flecks of calcification.⁷⁹ These tumors also have a soft consistency, so they can be mistaken for lipomas because of their tendency to change in size and shape at fluoroscopy.⁸²

NEURAL TUMOR

Neural tumors constitute 5% to 10% of benign gastric neoplasms.¹ Most are nerve sheath tumors (schwannomas, neuromas, or neurilemmomas). The tumors are composed histologically of Schwann cells with elongated nuclei that have a palisade arrangement. As they outgrow their blood supply, these tumors may undergo central necrosis and ulceration, causing GI bleeding. Most nerve sheath tumors are benign, but sarcomatous changes have occasionally been reported.¹

Neurofibromas are other less common neural tumors in the stomach. These tumors arise from sympathetic nerves of the Auerbach myenteric plexus or, less frequently, the Meissner plexus.⁸³ Gastric neurofibromas are usually small lesions detected as incidental findings at surgery or autopsy. Occasionally, however, these tumors may cause epigastric pain, nausea, vomiting, or upper GI bleeding.⁸³ They tend to be isolated lesions, but multiple neurofibromas may be present in the stomach and duodenum in patients with generalized neurofibromatosis (von Recklinghausen's disease).^{84,85} This condition is characterized by cutaneous, intracranial, or intraspinal neurofibromas, skin pigmentation, bone abnormalities, and other congenital malformations. About 10% of neurofibromas in the stomach eventually undergo malignant degeneration.⁸³ The risk of malignancy seems to be greatest in lesions associated with generalized neurofibromatosis.

Radiographic Findings

Neural tumors in the stomach usually appear on barium studies as discrete submucosal masses (with or without ulceration) that are indistinguishable from benign GISTs or other mesenchymal tumors (Fig. 31-22). However, some exogastric lesions may grow outward from the stomach, projecting as lobulated masses into the peritoneal cavity.⁸³ Others may have an hourglass or dumbbell configuration.⁸³ Although they are rare lesions, gastric and duodenal neurofibromas should be suspected when multiple submucosal masses are found in the stomach and duodenum in patients with cutaneous neurofibromas or other stigmata of neurofibromatosis (Fig. 31-23).

GRANULAR CELL TUMOR

Granular cell tumors are rare benign tumors that occur predominantly in the skin, tongue, breast, and subcutaneous tissues.⁸⁶ These tumors originally were called granular cell myoblastomas, but subsequent histochemical and electron microscopic data have indicated that they have a neural derivation, arising from Schwann cells.⁸⁷ The lesions consist histologically of sheets of polygonal tumor cells containing an eosinophilic-staining granular cytoplasm.⁸⁷ About 7% of granular cell tumors are located in the GI tract, including the esophagus, stomach, colon, appendix, and biliary tree.⁸⁸ Granular cell tumors in the stomach are usually found unexpectedly at surgery or autopsy.⁸⁹ Occasionally, however, ulcerated lesions may cause epigastric pain or upper GI bleeding.⁸⁹ Surgical resection is almost always curative.

Figure 31-22 Gastric neurofibroma. An ulcerated submucosal mass is seen en face in the antrum. This lesion cannot be distinguished from an ulcerated GIST. (Courtesy Sat Somers, MD, Ontario, Canada.)

Figure 31-23 Duodenal neurofibromas in a patient with neurofibromatosis. Multiple submucosal masses are present in the first and second portions of the duodenum. This patient also had cutaneous neurofibromas and other stigmata of neurofibromatosis. (Courtesy Seth N. Glick, MD, Philadelphia.)

Radiographic Findings

Granular cell tumors in the stomach usually appear on barium studies as discrete submucosal masses, ranging from 0.5 to 2.5 cm in size.⁸⁹ Occasionally, multiple granular cell tumors are present in the stomach (Fig. 31-24).⁹⁰ Despite their rarity, granular cell tumors should be suspected when one or more submucosal lesions are found in the stomach in patients who have additional lesions involving the skin, tongue, or breast.

INFLAMMATORY FIBROID POLYP

Inflammatory fibroid polyps are uncommon submucosal lesions characterized histologically by whorls of fibrous tissue and blood vessels associated with an inflammatory infiltrate containing a high percentage of eosinophils.⁹¹ These lesions tend to occur in the stomach but are also found in the small bowel and colon. Because of the histologic findings, inflammatory fibroid polyps have also been called eosinophilic granulomas and fibromas with eosinophilic infiltration.⁹² However, inflammatory fibroid polyps are unrelated to eosinophilic granulomas of the lung or bone, which are composed primarily of histiocytes rather than fibroblasts. These lesions are not associated with a peripheral eosinophilia, as is eosinophilic gastroenteritis, a separate and more diffuse condition.

Although the pathogenesis is uncertain, it has been postulated that inflammatory fibroid polyps have an allergic or inflammatory origin and are therefore not true neoplasms. One theory is that a localized break in the mucosa incites an inflammatory response in the adjacent submucosa, with connective tissue proliferation in the form of a polypoid mass. Whatever their origin, inflammatory fibroid polyps are benign lesions without any known risk of malignant degeneration.

Figure 31-24 Granular cell tumors. Several small submucosal masses (arrows) are present on the greater curvature of the stomach. This patient had additional granular cell tumors on the tongue.

Clinical Findings

Most patients with inflammatory fibroid polyps are asymptomatic, but some may present with epigastric pain or upper GI bleeding because of superficial ulceration of these lesions.⁹¹ Rarely, pedunculated polyps in the distal antrum may cause intermittent gastric outlet obstruction.⁹¹

Radiographic Findings

Inflammatory fibroid polyps in the stomach are usually located in the antrum, occurring as solitary lesions that range from 1 to 5 cm in size.^{93,94} The lesions may appear on barium studies as sessile or, less frequently, pedunculated polyps with a smooth or slightly lobulated contour (Fig. 31-25).^{93,94} As a result, they may be indistinguishable from adenomatous polyps in the stomach. Other inflammatory fibroid polyps that have a submucosal appearance may be indistinguishable from benign GISTs.⁹⁴ When these lesions are pedunculated, they may occasionally prolapse through the pylorus, causing gastric outlet obstruction. Rarely, inflammatory fibroid polyps are larger or more lobulated, mimicking the appearance of polypoid gastric carcinomas.⁹¹

ECTOPIC PANCREATIC REST

Although they are not true neoplasms, ectopic pancreatic rests are included in this chapter because they are submucosal lesions that are difficult to distinguish from GISTs or other mesenchymal tumors in the stomach and duodenum. Most ectopic pancreatic rests are discovered as incidental findings in patients seeking medical attention for other reasons. It may be necessary to resect these lesions, however, if they cause symptoms or if a neoplastic condition cannot be excluded on radiologic or endoscopic examinations.

Figure 31-25 Inflammatory fibroid polyp. A sessile, slightly lobulated polyp (arrow) is seen on the greater curvature of the gastric antrum. This lesion is indistinguishable from an adenomatous polyp in the stomach.

Pathology

Ectopic pancreatic rests consist histologically of all pancreatic elements, including acini, ducts, and islet cells, but ductal structures tend to be arranged more haphazardly in these lesions than in normal pancreatic tissue. Ectopic pancreatic rests are thought to result from abnormal embryologic development in which fragments of the ventral or dorsal pancreatic anlage are implanted in the intestinal wall.⁹⁵ These primitive epithelial buds may undergo varying degrees of differentiation toward mature glandular tissue. The term *adenomyosis* has been used to encompass a histologic spectrum of lesions, ranging from undifferentiated glandular epithelium to well-differentiated pancreatic tissue.⁹⁶ Lesions consisting of poorly differentiated acinar and ductal structures have been called adenomyomas, whereas well-differentiated nodules of pancreatic tissue have been called ectopic, heterotopic, or aberrant pancreatic rests.⁹⁶

Ectopic pancreatic rests occur throughout the GI tract, but about 80% are located in the stomach, duodenum, or proximal jejunum.⁹⁷ Occasionally, this anomaly is found in the gallbladder, biliary tree, liver, spleen, omentum, mesentery, appendix, or mediastinum, or even in a Meckel's diverticulum.⁹⁸

Clinical Findings

Most patients with ectopic pancreatic rests in the stomach or duodenum are asymptomatic, but some may present with epigastric pain or upper GI bleeding.^{99,100} It has been postulated that complications result from irritation or ulceration of the adjacent gastric or duodenal mucosa by pancreatic secretions.⁹⁵ Occasionally, lesions arising near the pylorus may cause gastric outlet obstruction.¹⁰¹ Rarely, ectopic pancreatic rests develop the same diseases that affect normal pancreatic tissue, including pancreatitis, pseudocysts, and benign or malignant pancreatic tumors.¹⁰² Because upper GI symptoms are more likely to be caused by peptic ulcer disease or other unrelated disorders, this anomaly should not be accepted as the source of the patient's symptoms without careful radiographic or endoscopic evaluation of the entire stomach and duodenum. Ectopic pancreatic rests should be resected only if the patient is symptomatic or if a significant neoplasm cannot be excluded nonoperatively.

Radiographic Findings

Ectopic pancreatic rests in the stomach and duodenum usually appear on barium studies as smooth, broad-based submucosal masses, closely resembling benign GISTs or other mesenchymal tumors (Fig. 31-26).^{95,97,103,104} They almost always occur as solitary lesions, ranging from 1 to 3 cm in size.¹⁰⁴ Ectopic pancreatic rests in the stomach tend to be located on the greater curvature of the distal antrum within 1 to 6 cm from the pylorus (see Fig. 31-26),^{103,104} whereas duodenal lesions are most frequently found in the proximal duodenum between the duodenal bulb and papilla of Vater.

Ectopic pancreatic rests in the stomach and duodenum often contain a central umbilication or dimple, representing the orifice of a primitive ductal system.^{103,104} In about 50% of patients, this orifice is manifested by a central collection of barium, ranging from 1 to 5 mm in diameter and 5 to 10 mm in depth.¹⁰³ When viewed en face, these umbilicated lesions have the typical bull's-eye appearance of ulcerated GISTs or other mesenchymal tumors. Rarely, barium may reflux into rudimentary ductal structures that terminate in tiny club-shaped

Figure 31-26 Ectopic pancreatic rest. The lesion appears as a discrete submucosal mass (arrows) on the greater curvature of the distal antrum. This is a characteristic location for ectopic pancreatic rests. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

pouches, a finding that is almost pathognomonic of ectopic pancreatic rests.⁹⁵

Differential Diagnosis

The presence of a centrally umbilicated submucosal mass on the greater curvature of the distal gastric antrum within 1 to 6 cm from the pylorus should be highly suggestive of an ectopic pancreatic rest. Benign GISTs on the greater curvature may produce similar findings, but these lesions often contain areas of ulceration, and their location in the stomach is more variable. Other conditions such as metastatic disease and lymphoma may also be manifested by bull's-eye lesions, but these patients usually have multiple lesions in the stomach and duodenum, whereas ectopic pancreatic rests almost always occur as solitary lesions. Rarely, ectopic pancreatic rests that are found elsewhere in the stomach and are larger or more lobulated may be indistinguishable from benign or malignant gastric tumors.¹⁰⁵ If the radiographic findings are equivocal, endoscopy and biopsy should be performed for a more definitive diagnosis.

BRUNNER GLAND HYPERPLASIA (BRUNNER GLAND HAMARTOMA)

Brunner glands in the duodenum normally secrete an alkaline mucus that protects the mucosa from the damaging effects of acidic gastric juices entering the duodenum. Brunner gland hyperplasia is therefore thought to occur as a response to hypersecretion of acid in the stomach.¹⁰⁶ However, hyperchlorhydria has been documented by gastric analysis in less than 50% of patients with this condition,¹⁰⁷ so a causal relationship between gastric hyperacidity and Brunner gland hyperplasia has not been proved.

Pathology

Hyperplastic Brunner glands may be manifested grossly by diffuse enlargement of Brunner glands throughout the proximal duodenum or by massive enlargement of a single gland. In

the past, solitary lesions were called Brunner gland adenomas.^{108,109} However, pathologic examination of these lesions has revealed an intimate admixture of ducts, acini, smooth muscle, and adipose tissue without evidence of cellular atypia, so many investigators now believe that these lesions should be classified as hamartomas rather than as true neoplasms.^{110,111} Their hamartomatous origin is supported by the absence of malignant degeneration in these enlarged glands. Nevertheless, Brunner gland hamartomas are important because they can be mistaken for neoplastic lesions on radiologic or endoscopic examination and because they may occasionally cause symptoms.

Clinical Findings

Except for its association with duodenal ulcers and gastric hypersecretory states,¹⁰⁶ the diffuse form of Brunner gland

hyperplasia has no clinical significance. In contrast, solitary Brunner gland hamartomas may occasionally cause obstructive symptoms, epigastric pain, or upper GI bleeding because of ulceration of the overlying mucosa.^{108,111,112} Although the diffuse form of Brunner gland hyperplasia requires no specific treatment, solitary lesions should be resected if they cause symptoms or if the pathologic diagnosis is in doubt.¹¹¹ An endoscopic polypectomy may be feasible if the lesion is small or pedunculated, but surgery may be required for larger lesions.^{111,112}

Radiographic Findings

The diffuse form of Brunner gland hyperplasia is manifested on barium studies by multiple small, rounded nodules in the proximal duodenum, producing a characteristic cobblestone or Swiss cheese appearance (Fig. 31-27A).^{113,114} The nodules

Figure 31-27 Brunner gland hyperplasia: spectrum of findings. **A.** Multiple tiny, rounded nodules are present in the duodenal bulb in a patient with diffuse Brunner gland hyperplasia. **B.** This patient has several Brunner gland hamartomas in the duodenum, manifested by submucosal masses (arrows) in the bulb. **C.** A large polypoid defect (arrows) is seen in the duodenal bulb in another patient with a giant Brunner gland hamartoma. **D.** A fourth patient with enlarged Brunner glands has markedly thickened, disorganized folds in the descending duodenum because of concomitant duodenitis. (**A** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992; **C** courtesy Jackie Brown, MD, Vancouver, Canada; **D** courtesy Dean D. T. Maglinte, MD, Indianapolis.)

tend to be most abundant in the duodenal bulb, with fewer nodules in the descending duodenum, so the lesions correspond to the normal anatomic distribution of Brunner glands.¹¹³ Occasionally, central flecks of barium may be identified in the nodules. In these cases, it has been postulated that these lesions represent chronic duodenal erosions in various stages of reepithelialization.¹¹⁵

Brunner gland hamartomas may appear as one or more submucosal or sessile lesions, ranging from several millimeters to several centimeters in size (Fig. 31-27B).^{109,111,113,114,116,117} Some patients with giant Brunner gland hamartomas may have large polypoid defects in the duodenum (Fig. 31-27C).¹¹⁸ Other patients with enlarged Brunner glands may have markedly thickened, irregular folds in the proximal duodenum because of concomitant duodenitis (Fig. 31-27D).¹¹⁷ Rarely, large intramural masses may cause mechanical obstruction of the duodenum or act as the lead point for a duodenojejunal intussusception.^{111,116,119}

Differential Diagnosis

The differential diagnosis for the diffuse form of Brunner gland hyperplasia includes the various polyposis syndromes, benign lymphoid hyperplasia, heterotopic gastric mucosa, and nodular duodenitis. Although the polyposis syndromes may be manifested by multiple rounded nodules in the duodenum, these patients almost always have a generalized intestinal polyposis, whereas Brunner gland hyperplasia is confined to the duodenum. Similarly, benign lymphoid hyperplasia is characterized by multiple small nodules in the duodenal bulb and proximal duodenum (Fig. 31-28).¹²⁰ However, these patients often have generalized lymphoid hyperplasia of the small bowel or colon. Unlike Brunner's glands, heterotopic gastric mucosa in the duodenum is characterized by angulated or polygonal 1- to 5-mm nodules or plaques that tend to be clustered near the base of the duodenal bulb (Fig. 31-29).^{121,122} Finally, nodular duodenitis may be manifested by thickened nodular folds that can resemble hyperplastic Brunner glands. However, the nodular folds tend to coalesce in the inflamed duodenum, whereas enlarged Brunner glands have more discrete borders.

Solitary Brunner gland hamartomas are difficult to distinguish from other polypoid lesions in the duodenum. Depending on their appearance, they can resemble mucosal lesions such as adenomatous polyps or submucosal lesions such as benign GISTs. Occasionally, prolapsed gastric mucosa in the duodenal bulb may produce a similar appearance. However, prolapsed mucosa is usually recognized as a mushroom-shaped defect at the base of the bulb that occurs as a transient finding at fluoroscopy (see Fig. 31-9). Rarely, a pedunculated polyp in the gastric antrum that has prolapsed into the duodenum can also be mistaken for a Brunner gland hamartoma.³

DUPLICATION CYST

Duplication cysts are hollow, epithelium-lined, spherical or tubular structures that are directly attached to some portion of the GI tract, usually the distal ileum.^{123,124} They tend to occur on the mesenteric border of the bowel, often sharing a common blood supply and muscular coat with the adjacent bowel wall. Most duplication cysts are spherical duplications that have no direct communication with the normal GI

Figure 31-28 Benign lymphoid hyperplasia. Innumerable tiny nodules are present in the duodenal bulb. This patient had hypogammaglobulinemia. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 31-29 Heterotopic gastric mucosa in the duodenum. There are discrete, angulated filling defects near the base of the duodenal bulb. This appearance is so characteristic of heterotopic gastric mucosa that a confident diagnosis can be made on the basis of double-contrast studies without need for endoscopy. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

tract.^{124,125} However, the rare tubular form of duplication cyst may communicate with the GI lumen at its proximal or distal end.^{124,125}

Duplication cysts of the stomach and duodenum are uncommon lesions, comprising only 4% to 5% of all intestinal duplications.^{125,126} However, they may be associated with a variety of

complications such as bleeding, obstruction, or perforation. These lesions should therefore be surgically repaired or removed whenever feasible.

Pathology

GI duplication cysts are congenital malformations, probably resulting from faulty embryologic budding or defective recanalization of the alimentary tube during early fetal life.^{124,127,128} Histologically, they are fluid-filled cysts containing a well-developed smooth muscle layer and mucous membrane lining. This mucous membrane is usually identical to that of the parent bowel, but duplication cysts may occasionally contain gastric, intestinal, pancreatic, or even respiratory epithelium.^{124,129} When ectopic gastric mucosa is present in the cyst, secretion of peptic acid may cause ulceration or bleeding.¹²⁹ Depending on the volume of secretions within the cysts, they may vary from 1 to 25 cm in size.¹²⁹ Gastric duplication cysts usually arise from the greater curvature of the antrum or body,^{123,126} whereas duodenal duplication cysts usually arise from the medial aspect of the first or second portion of the duodenum.^{125,127,129}

Duplication cysts of the stomach and duodenum may be associated with a variety of other congenital anomalies, including intestinal or biliary atresia, malrotation, imperforate anus, double gallbladder, and double uterus. These patients also tend to have duplication cysts elsewhere in the GI tract.¹³⁰ Unlike mediastinal duplication cysts, those in the stomach and duodenum are rarely associated with hemivertebrae or other vertebral anomalies.^{126,129}

Clinical Findings

Gastric duplication cysts are twice as common in women as in men,¹³⁰ whereas duodenal duplication cysts have an approximately equal gender distribution.¹²⁷ Because most gastric duplication cysts cause symptoms during the first year of life, they are almost always diagnosed during early childhood.^{126,130} In contrast, 35% to 40% of duodenal duplication cysts are discovered in patients over 20 years of age.^{129,131}

Children or adults with duplication cysts of the stomach or duodenum typically present with a palpable abdominal mass and vomiting as the enlarging cyst encroaches on the adjacent stomach or duodenum.^{126,127,129,130} In infants with gastric duplication cysts, nonbilious vomiting may erroneously suggest hypertrophic pyloric stenosis.¹³² In contrast, duodenal duplication cysts tend to be associated with bilious vomiting.¹²⁵ Less frequently, older children or adults may present with abdominal pain, weight loss, fever, or upper GI bleeding.^{125-127,129,130} Abdominal pain most likely results from progressive distention of the cyst by its own secretions. Fever occurs if the cyst becomes infected. Upper GI bleeding is caused by localized pressure necrosis of the adjacent gastric or duodenal wall or by ulceration of a cyst that communicates directly with the stomach or duodenum.^{125,127} Occasionally, duodenal duplication cysts may compress the ampulla of Vater or the pancreatic or common bile ducts, causing acute pancreatitis or obstructive jaundice.^{127,129} Rarely, duplication cysts may present as surgical emergencies because of torsion or perforation of the cyst with associated peritonitis.^{129,133}

Because of these complications, duplication cysts of the stomach and duodenum should be treated surgically. Gastric duplication cysts can often be excised without difficulty from their attachment to the greater curvature of the stomach.¹³⁰

Because of their proximity to the ampulla of Vater, however, duodenal duplication cysts frequently cannot be resected without performing a pancreaticoduodenectomy and reconstructive biliary surgery. Alternatively, some surgeons prefer to create a window between the cyst and duodenum by excising a portion of the common wall between these structures to permit internal drainage and decompression of the cyst.^{125,129}

Radiographic Findings

Duplication cysts of the stomach and duodenum may occasionally be recognized on abdominal radiographs by curvilinear calcification in the cyst wall.^{134,135} However, calcification is more commonly seen in mesenteric, renal, or adrenal cysts.

Gastric duplication cysts typically appear on barium studies as intramural or extrinsic mass lesions involving the greater curvature or, less commonly, the posterior wall or lesser curvature of the gastric antrum (Fig. 31-30A).^{123,136} Similarly, duodenal duplication cysts may be recognized as smooth intramural or extrinsic masses involving the medial wall of the descending duodenum (Fig. 31-31).^{125,129,131} As gastric and duodenal duplication cysts enlarge, they may encroach considerably on the lumen of the stomach and duodenum, causing progressive obstruction. Rarely, communicating duplication cysts can be recognized as ovoid or tubular barium-filled structures adjacent to the stomach or duodenum because of opacification of the cyst lumen (Fig. 31-32).^{137,138}

Both ultrasonography and CT may be helpful in confirming the cystic nature of gastric and duodenal duplication cysts that are visualized indirectly on barium studies. These structures usually appear on ultrasound examination as sonolucent masses with strong posterior wall echoes and through-transmission.^{138,139} In some patients, the mucosal lining of the cyst is manifested by an echogenic inner ring surrounded by a relatively hypoechoic muscle layer.^{138,139} Echogenic internal components may occasionally be seen in cysts that are infected or hemorrhagic.¹³⁹ Duplication cysts can also be recognized by CT as thin-walled, fluid-filled structures abutting the greater curvature of the stomach or medial wall of the descending duodenum (see Fig. 31-30B).^{135,137,140} Rarely, CT may demonstrate cyst wall calcification or enteroliths within the cyst.¹⁴⁰

Differential Diagnosis

The finding on barium studies of a smooth intramural lesion on the greater curvature of the gastric antrum or medial wall of the descending duodenum should suggest the possibility of a duplication cyst, particularly in children. Other intramural lesions (e.g., benign GISTs, lipomas, or hematomas) or extrinsic lesions (e.g., pancreatic tumors or pseudocysts or choledochal cysts) involving the stomach or duodenum may produce similar findings. When duplication cysts are suspected on barium studies, ultrasonography or CT may be helpful for documenting the cystic nature of these structures. Other cystic lesions in the upper abdomen, such as choledochal cysts, mesenteric cysts, omental cysts, and pancreatic pseudocysts, may resemble duplication cysts on ultrasound or CT studies.^{139,140} Nevertheless, the finding of a cystic mass contiguous with the greater curvature of the stomach or medial wall of the duodenum, but separable from the gallbladder, extrahepatic biliary tree, and pancreas, should be highly suggestive of a duplication cyst.

Figure 31-30 Gastric duplication cyst. **A.** Barium study shows a smooth mass (arrows) indenting the posterior wall of the gastric fundus. **B.** CT scan shows a thin-walled, fluid-filled mass (arrow) abutting the stomach. (From Thornhill BA, Cho KC, Morehouse HT: Gastric duplication associated with pulmonary sequestration: CT manifestations. *AJR* 138:1168–1171, 1982.)

Figure 31-31 Duodenal duplication cyst. There is a large intramural mass (arrows) in the descending duodenum. Note the smooth contour of the lesion. An intramural hematoma or choledochal cyst could produce similar findings.

Figure 31-32 Communicating gastric duplication. Barium has entered a long, tubular duplication cyst (short arrows) on the greater curvature of the stomach. The duplication extends from the fundus to the pylorus, where it communicates with the lumen (long arrow). This form of duplication is extremely uncommon. (From Marshak RH, Lindner AE, Maklansky D [eds]: *Radiology of the Stomach*. Philadelphia, WB Saunders, 1983.)

Differential Diagnosis

Staging

Treatment and Prognosis

Duodenal Carcinoma

Gastric Carcinoma

There has been a dramatic decline in the incidence of gastric carcinoma since the late 1940s.¹⁻⁴ Nevertheless, it remains a deadly disease, with overall 5-year survival rates of less than 20%.⁴⁻⁸ Since the 1980s, attention has been focused on the role of double-contrast barium studies and endoscopy for the early diagnosis of gastric cancer. The Japanese have had tremendous success in detecting early gastric cancer by mass screening of the adult population with these techniques. However, it is difficult to justify such screening programs outside Japan because of the lower incidence of this malignancy. Thus, the prognosis for gastric carcinoma remains dismal in most parts of the world.

EPIDEMIOLOGY

Gastric carcinoma has striking geographic variations, with the highest incidences reported in Japan, Chile, Finland, Poland, and Iceland.^{3,8} However, Japanese immigrants and their offspring living in the United States have a significantly lower incidence of gastric cancer than those living in Japan.^{8,9} Such epidemiologic data suggest that environmental factors have a major role in the development of gastric carcinoma. Dietary habits may be particularly important in explaining the observed geographic differences in cancer risk. *Helicobacter pylori* infection of the stomach has also increasingly been implicated as a major risk factor in the development of gastric carcinoma in various parts of the world. Other predisposing conditions include atrophic gastritis, pernicious anemia, gastric polyps, partial gastrectomy, Ménétrier's disease, and hereditary factors. These risk factors for gastric cancer are discussed separately in the following sections.

DIETARY FACTORS

Studies have shown that diets rich in salted, smoked, or poorly preserved foods are associated with an increased risk of gastric cancer,^{4,10,11} whereas diets rich in fruits and vegetables are associated with a decreased risk.^{4,12} Foods containing nitrates or nitrites have also been implicated in the development of gastric cancer.^{4,9} These compounds are converted by bacteria to nitrosamines, which are thought to have a carcinogenic effect on the stomach.¹³ Thus, populations with a higher average intake of nitrates and nitrites probably have a higher gastric cancer risk. Conversely, vitamin C (ascorbic acid) appears to have a protective effect by reducing nitrites to nitric oxide and preventing the formation of nitrosamine compounds.¹⁴ This could explain why the consumption of fruit and vegetables is associated with a lower risk of developing gastric cancer. One study also found that a high intake of cereal fiber is associated with a significantly lower risk of carcinoma of the cardia,¹⁵ possibly because of the nitrite-scavenging properties of cereal fiber.

Helicobacter pylori Gastritis

H. pylori has increasingly been implicated as a major risk factor in the pathogenesis of gastric carcinoma; *H. pylori* is thought to be the leading cause of gastric cancer worldwide.¹⁶ Various studies have found that people with *H. pylori* gastritis have a two to six times greater risk of developing gastric cancer than those without this infection.¹⁷⁻¹⁹ It has been well documented that people with long-standing *H. pylori* gastritis are more likely to develop atrophic gastritis.^{16,20,21} Over a period of years, chronic atrophic gastritis may progress to gastric atrophy, intestinal metaplasia, dysplasia, and, eventually, gastric carcinoma.^{4,22-24} Other studies have found that people with *H. pylori* gastritis are more likely to develop the intestinal type of gastric carcinoma than people without this infection (see later, "Gastric Carcinoma: Pathology").^{25,26} It has also been shown that certain strains of *H. pylori*, which produce a vacuolating cytotoxin, cytotoxin-associated gene A (*cagA*), are associated with a higher prevalence of atrophic gastritis and gastric carcinoma.^{27,28} A meta-analysis of 16 studies from the literature found that infection with *cagA*-positive strains of *H. pylori* substantially increased the risk of gastric cancer compared to the risk associated with *H. pylori* infection irrespective of *cagA* status.²⁹

Nevertheless, gastric cancer develops in only a tiny percentage of all people with *H. pylori* gastritis, so other genetic or environmental factors presumably have a role in cancer pathogenesis. In a cost-effectiveness model, Parsonnet and colleagues found that widespread screening and treatment of adults for *H. pylori* is a potentially cost-effective strategy for the prevention of gastric cancer, particularly in high-risk populations.³⁰

However, further investigation is needed to determine whether such an approach is justified.

Atrophic Gastritis

Atrophic gastritis has been classified into two types, which have different histologic, immunologic, and secretory characteristics. Type A gastritis is usually associated with pernicious anemia (see next section). In contrast, type B gastritis (which is more common) predominantly involves the antrum and usually results from mucosal injury by *H. pylori* or, less commonly, by other toxic agents (see Chapter 30).³¹ Long-term studies indicate that about 10% of patients with type B gastritis develop gastric carcinoma within 10 to 20 years.^{32,33} It has been postulated that chronic atrophic gastritis leads to the development of intestinal metaplasia, dysplasia, and, eventually, adenocarcinoma.^{4,22,23} This pathologic sequence of events is supported by the frequent association of gastric carcinoma and intestinal metaplasia on surgical specimens.^{22,23} Thus, chronic atrophic gastritis and intestinal metaplasia are thought to be important precursor conditions for the development of gastric carcinoma.

Pernicious Anemia

Type A gastritis predominantly involves the gastric fundus and body and is usually thought to result from immunologic injury by antiparietal cell antibodies in patients with pernicious anemia.³¹ This type of gastritis may also be associated with an increased risk of gastric cancer. In various studies, the incidence of gastric cancer in patients with pernicious anemia has been two to three times greater than that expected for the general population.^{34,35} Most such tumors involve the gastric fundus or body. Although some investigators advocate radiologic or endoscopic surveillance of patients with known pernicious anemia, others believe that the cancer risk is not high enough to warrant routine surveillance.³⁶ Nevertheless, any patient with pernicious anemia who has guaiac-positive stool or other upper gastrointestinal (GI) complaints should be aggressively evaluated for possible gastric carcinoma.

Gastric Polyps

Adenomatous polyps account for less than 20% of all gastric polyps.³⁷ Despite their rarity, these polyps are premalignant lesions that are capable of undergoing malignant degeneration via an adenoma-carcinoma sequence similar to that found in the colon.³⁸ Nearly 50% of gastric adenomas larger than 2 cm are found to harbor carcinomatous foci.^{39,40} All adenomatous polyps should therefore be resected because of the risk of malignant transformation. Nevertheless, adenocarcinoma is about 30 times more common than adenomatous polyps in the stomach, so most gastric cancers are thought to originate *de novo* and not from preexisting polyps.³⁸

Partial Gastrectomy

Patients who undergo partial gastrectomy appear to be at increased risk for the development of gastric carcinoma. A gastric stump cancer is defined as a primary carcinoma of the gastric remnant occurring a minimum of 5 years after partial gastrectomy for gastric ulcers or other benign disease.⁴¹ Affected individuals have usually undergone a Billroth II rather than a Billroth I procedure.^{42,43} These tumors tend to be located in the distal portion of the gastric remnant near the gastrojejunal anastomosis. It has been postulated that recurrent bile reflux

above the anastomosis causes chronic gastritis, intestinal metaplasia, and, eventually, gastric carcinoma. In various studies, the mortality from gastric cancer 15 years or more after partial gastrectomy has been three to seven times greater than that expected for the general population.⁴³⁻⁴⁵ Some authors therefore advocate routine endoscopic surveillance of the gastric remnant starting 15 years after surgery.⁴⁵ However, other investigators have found no greater incidence of gastric carcinoma than that expected for the general population as long as 25 years after surgery.⁴⁶ Thus, the need for surveillance in these patients remains controversial.

Gastric carcinoma has also been reported as a late complication of gastrojejunostomy for benign disease in the absence of partial gastrectomy.^{47,48} As in patients who have undergone a Billroth II procedure, bile reflux gastritis and intestinal metaplasia are thought to be predisposing factors. Whatever the explanation, the risk of developing gastric carcinoma also appears to be increased in patients who undergo a gastrojejunostomy without a gastric resection.

Ménétrier's Disease

Ménétrier's disease is a rare disorder of unknown etiology characterized by a hypertrophic gastropathy associated with decreased gastric acid secretion and a protein-losing enteropathy (see Chapter 30). Anecdotal cases of gastric carcinoma have been described in patients with Ménétrier's disease.⁴⁹ However, it is unclear whether this association is coincidental or whether Ménétrier's disease is a premalignant condition.

Hereditary Factors

Hereditary factors have also been implicated in the development of gastric cancer because a positive family history has been associated with an increased risk of this malignancy.⁵⁰ In one study, the prevalence of *H. pylori* gastritis was significantly higher in subjects who had parents with gastric cancer than in other subjects.⁵¹ Such findings suggest that familial aggregation of gastric cancer may be explained at least partly by familial clustering of *H. pylori* gastritis. Patients with gastric cancer also have been found to have a higher frequency of blood type A and a lower frequency of blood type O than the general population.⁵²

PATHOLOGY

Gross Features

Most gastric carcinomas are polypoid or ulcerated lesions.⁵³⁻⁵⁵ Polypoid carcinomas have a plaque-like, lobulated, or fungating appearance. Ulcerated carcinomas may contain deep, irregular or broad, shallow areas of ulceration caused by necrosis and excavation of the tumor.⁵³ The ulcer may be surrounded by a thin rind of malignant tissue or by an obvious mass lesion, so many polypoid tumors have ulcerated components. Less commonly, gastric carcinomas may be diffusely infiltrative lesions that spread along the gastric wall with relatively little intraluminal growth.⁵³ These scirrhous tumors may produce a classic linitis plastica appearance because of submucosal thickening and fibrosis incited by the tumor. Other gastric carcinomas may be superficial spreading lesions that are confined to the mucosa or submucosa without invading the deep muscle layers of the gastric wall.⁵³

Rarely, patients with gastric carcinoma have multiple primary lesions separated by normal intervening mucosa. In various

series, two or more synchronous tumors have been found in 2% to 8% of all patients with gastric cancer.^{56,57} In such cases, individual lesions may have different morphologic features.

Histologic Features

More than 95% of malignant neoplasms in the stomach are adenocarcinomas.³ The remaining lesions consist of lymphoma, gastrointestinal stromal tumors (GISTs), Kaposi's sarcoma, carcinoid, and other rare malignant tumors (see Chapter 33). Gastric carcinomas may be classified into two types: (1) an intestinal type characterized by well-formed glandular structures that tend to grow in a fungating manner; and (2) a diffuse type characterized by poorly cohesive cells that tend to infiltrate and thicken the gastric wall without producing a discrete mass.⁵⁸ Intestinal-type lesions are more likely to involve the distal stomach and are often associated with underlying atrophic gastritis. In contrast, diffuse-type lesions are more likely to involve the entire stomach (especially the gastric cardia) and tend to have a worse prognosis.⁵⁹

Gastric carcinomas have been further classified by the World Health Organization into the following subtypes—papillary, tubular, mucinous, and signet ring cell.⁶⁰ Most tumors that are capable of forming glandular structures secrete mucinous substances and, occasionally, excessive mucin accumulates extracellularly in colloid or mucinous adenocarcinomas.⁵³ Other adenocarcinomas are composed of distinctive signet ring cells containing large amounts of intracytoplasmic mucin and compressed, eccentric nuclei.⁵³ As they infiltrate the gastric wall, these signet ring cells often incite a desmoplastic response in the submucosa and muscularis propria, producing the classic pathologic features of a primary scirrhous carcinoma. In various series, scirrhous tumors have been found to account for 5% to 15% of all gastric cancers.^{5,7}

Most adenocarcinomas of the stomach are diagnosed at an advanced stage. By definition, advanced gastric cancers have already invaded the muscularis propria. These tumors are usually associated with metastases to regional lymph nodes or other local or distant structures. In contrast, early gastric cancers are defined histologically as cancers in which malignant invasion is limited to the mucosa or submucosa, regardless of the presence or absence of lymph node metastases.^{61,62} The largest number of early gastric cancers has been reported in Japan as a result of mass screening of the adult population. Unlike advanced carcinomas, which have a dismal prognosis, early gastric cancers are curable lesions with 5-year survival rates greater than 90% (see later, “[Treatment and Prognosis](#)”).

Distribution

At one time, most gastric carcinomas were located in the antrum.⁶³ Since the late 1940s, however, there has been a gradual shift in the distribution of gastric cancer from the antrum proximally to the body and fundus.^{1,63,64} This changing distribution has been attributed primarily to a rising incidence of carcinoma of the gastric cardia, which has increased at a rate exceeding that of any other cancer.^{4,65-67} As a result, these tumors now have a relatively even distribution in the stomach, with about 30% located in the antrum, 30% in the body, and 40% in the fundus or cardiac region.^{1,6,7,64} This changing pattern of disease has important implications for cancer detection because the gastric cardia and fundus must be carefully evaluated for signs of malignancy in all patients who undergo barium studies or endoscopy to rule out gastric carcinoma.

ROUTES OF SPREAD

Gastric carcinoma may invade local, regional, or distant structures by four pathways—direct extension, lymphatic spread, intraperitoneal seeding, and hematogenous metastases. The various pathways of spread are discussed separately in the following sections.

Direct Extension

Gastric carcinoma has a tendency to invade adjacent structures such as the liver, pancreas, and spleen.^{55,68} Longitudinal spread of tumor along the GI tract is also relatively common. The distal esophagus is directly involved by carcinoma of the cardia in about 60% of patients,⁶⁹ whereas the duodenum is involved by carcinoma of the antrum in 5% to 25% of patients.⁷⁰⁻⁷² Tumor involving the greater curvature of the stomach may also spread inferiorly via the gastrocolic ligament to the transverse colon, occasionally resulting in the development of a gastrocolic fistula.⁷³

Lymphatic Spread

Because of the abundant lymphatics in the stomach, lymph node metastases are found in 74% to 88% of patients with gastric carcinoma.⁵³ These patients may initially have involvement of local (perigastric) nodes and, subsequently, regional (celiac, hepatic, left gastric, and splenic) or distant (left supraclavicular and left axillary) nodes.⁸ The frequency of lymphatic metastases is related to the size and depth of penetration of the tumor. Nevertheless, lesions are still classified histologically as early gastric cancers, regardless of the presence of local lymph node metastases, if malignant invasion is confined to the mucosa or submucosa.⁶¹

Intraperitoneal Seeding

Patients with advanced gastric carcinoma may develop malignant ascites, resulting in intraperitoneal-seeded or omental metastases.⁶⁸ Diffuse carcinomatosis may also lead to the development of small bowel obstruction. Some patients with signet ring cell adenocarcinomas have bilateral “drop” metastases to the ovaries, known as Krukenberg tumors.⁷⁴ Although other malignant tumors can also have drop metastases to the ovaries, gastric carcinoma is responsible for most cases.⁷⁴ Some patients with gastric carcinoma may present with bilateral ovarian masses as the initial manifestation of their disease.

Hematogenous Metastases

Because the stomach is drained by the portal vein, the liver is the most common site of hematogenous (blood-borne) metastases from gastric carcinoma.⁵⁵ Other less common sites of hematogenous spread include the lungs, adrenals, kidneys, bones, and brain.

CLINICAL FINDINGS

Gastric carcinoma is usually considered a disease of middle and late life, with a peak incidence between 50 and 70 years of age.^{8,54,75} However, 3% to 5% of patients with gastric cancer are less than 35 years of age and 1% are less than 30 years of age.⁷⁶⁻⁷⁸ The percentage of young patients with gastric cancer has more than doubled since 1970.⁷⁷ For reasons that are unclear, these young people tend to have more aggressive lesions that are associated with a worse prognosis than most gastric cancers.^{77,78}

Gastric carcinoma is twice as common in men as in women.^{2,8,11} The male predilection of these tumors is even greater for carcinoma of the cardia, which is seven times more likely to occur in men than in women.^{79,80} This explanation for this discrepancy is unclear.

Most patients with gastric carcinoma are symptomatic only when they have advanced tumors with local or distant metastases.^{8,9} The most common presenting findings include epigastric pain, bloating, early satiety, nausea, vomiting, dysphagia, anorexia, weight loss, and signs or symptoms of upper GI bleeding, such as hematemesis, melena, guaiac-positive stool, and iron deficiency anemia.^{8,9,54} However, similar findings may be caused by ulcers, gastritis, or other benign conditions. As a result, there is often a considerable lag between the onset of symptoms and the diagnosis of gastric cancer.

The clinical presentation is also affected by the location and morphologic features of the tumor. For example, nausea and vomiting are common findings in patients with obstructing lesions involving the distal antrum or pyloric region.⁴ In contrast, patients with scirrhous carcinomas may develop early satiety because of the decreased compliance of a stomach that is diffusely infiltrated by tumor.⁸¹ Other patients with carcinoma of the cardia may present with recent onset of dysphagia caused by tumor obstructing the cardia.^{82,83} Some individuals with dysphagia may complain of food sticking behind the sternum, whereas others may have a sensation of blockage referred upward to the thoracic inlet or even the pharynx. The gastric cardia and fundus should therefore be carefully evaluated in all patients with dysphagia, regardless of the subjective site of obstruction, to rule out a carcinoma of the cardia masquerading as an esophageal or pharyngeal disorder.

Some patients with advanced gastric cancer may initially present with signs or symptoms of metastatic disease, such as anorexia, weight loss, abdominal masses, hepatic enlargement, jaundice, ascites, back pain, or neurologic findings. Patients with ovarian metastases may have bilateral pelvic masses (so-called Krukenberg tumors), and patients with drop metastases to the rectosigmoid colon may have a palpable Blumer's shelf on rectal examination.

ENDOSCOPIC FINDINGS

When brushings and biopsy specimens are obtained, endoscopy has a reported overall sensitivity of 94% to 98% in the diagnosis of gastric carcinoma.⁸⁴⁻⁸⁷ However, multiple biopsy specimens should be taken from suspicious lesions to decrease the risk of sampling error. It should also be recognized that endoscopy is a much less reliable technique for diagnosing scirrhous tumors than other gastric carcinomas. In various series, the sensitivity of endoscopic brushings and biopsy specimens in detecting these lesions has ranged from only 33% to 70%.⁸⁸⁻⁹⁰ False-negative histologic findings may occur not only because these scirrhous carcinomas are located predominantly in the submucosa, but also because the tumor cells are often separated by sheets of fibrosis. In some cases, multiple endoscopic examinations may be required for a definitive histologic diagnosis.⁹⁰ Thus, excessive reliance on negative endoscopic biopsy specimens may cause inordinate delays in the treatment of these patients. Finally, the presence and extent of tumor is often underestimated on the basis of the gross endoscopic findings because the mucosa overlying these lesions usually appears normal.⁹¹

RADIOGRAPHIC FINDINGS

Early Gastric Cancer

The double-contrast upper GI examination has been widely recognized as the best radiologic technique for the diagnosis of early gastric cancer.⁹²⁻⁹⁵ The Japanese Endoscopic Society has divided these lesions into three basic types.⁹⁶ Type I lesions are elevated lesions that protrude more than 5 mm into the lumen. Type II lesions are superficial lesions that are further subdivided into three groups—types IIa, IIb, and IIc—depending on their morphologic features. Type IIa lesions are elevated but protrude less than 5 mm into the lumen. Type IIb lesions are essentially flat. Type IIc lesions are slightly depressed but do not penetrate beyond the muscularis mucosae. Type III lesions are true mucosal ulcerations, with the ulcer penetrating the muscularis mucosae but not the muscularis propria. When early gastric cancers exhibit more than one of these morphologic features, they may have a dual classification, with the most predominant pattern listed first (e.g., type III + IIc).

Type I early gastric cancers typically appear as small, elevated lesions in the stomach.^{93,94} Because adenomatous polyps may undergo malignant degeneration (see earlier, "Gastric Polyps"), the possibility of early gastric cancer should be suspected for any sessile or pedunculated polyps larger than 1 cm. Other type I lesions may protrude considerably into the lumen and still be classified histologically as early gastric cancers (Fig. 32-1A).⁹⁴ Thus, polypoid carcinomas cannot be diagnosed definitively as early or advanced lesions on the basis of the radiographic findings.

Type II early gastric cancers are superficial lesions with elevated (IIa), flat (IIb), or depressed (IIc) components. These lesions may be manifested by plaque-like elevations, mucosal nodularity, shallow areas of ulceration, or some combination of these findings (Fig. 32-1B and C).⁹²⁻⁹⁵ Occasionally, type II lesions may be quite extensive and involve a considerable surface area of the stomach.

Type III early gastric cancers are characterized by shallow, irregular ulcer craters with nodularity of the adjacent mucosa and clubbing, fusion, or amputation of radiating folds (Fig. 32-1D).^{93,94} Careful analysis of the radiographic findings usually allows these lesions to be distinguished from benign gastric ulcers, which have different radiographic features (see Chapter 29). Although some lesions with an equivocal or suspicious appearance are found to be benign ulcers, endoscopy and biopsy should be performed for all lesions with suspicious radiographic findings to avoid missing early cancers.

About 70% of the ulcers in type IIc or III early gastric cancers are reported to undergo substantial healing on medical treatment.⁹⁷ It has been postulated that these cancers are characterized by a cycle of ulceration, healing, and recurrent ulceration. Rarely, complete healing of malignant ulcers has also been described.⁹⁷ However, malignant tumors should still be suspected on follow-up barium studies if mucosal nodularity or other abnormalities are detected at the site of the previous ulcer.

Japanese researchers have reported an incidence of early gastric cancer (i.e., the percentage of all gastric cancers detected as early lesions) of 25% to 46%⁹⁸⁻¹⁰¹ compared with an incidence of only 5% to 24% in Western countries.^{93-95,102-108} This discrepancy can be attributed to mass screening of the adult population in Japan because of the unusually high prevalence of gastric carcinoma in that country. Occasionally, early gastric cancers

Figure 32-1 Early gastric cancers. **A.** A type I lesion is seen as a polypoid mass (arrow) on the greater curvature of the gastric body. Despite its size, this lesion was found to be an early cancer. **B.** A type IIa lesion is manifested by a focal cluster of shallow elevations and nodules (arrows) in the gastric body. **C.** A type IIc lesion is manifested by shallow, irregular areas of ulceration and nodularity (arrows) in the gastric antrum. **D.** A type III lesion is seen as a scalloped, irregular antral ulcer with nodular, clubbed folds surrounding the ulcer crater. (A courtesy Kyunghee C. Cho, MD, Newark, NJ; B from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992; D from Levine MS, Creteur V, Kressel HY, et al: *Benign gastric ulcers: diagnosis and follow-up with double-contrast radiography. Radiology* 164:9–13, 1987.)

Figure 32-2 Findings of gastric carcinoma on abdominal radiographs. **A.** Close-up view from an abdominal radiograph shows a soft tissue mass (arrows) indenting the lesser curvature of the gas-filled stomach. This was a polypoid gastric carcinoma. **B.** In another patient, the gas-filled stomach has a narrowed, tubular appearance (arrow) caused by a scirrhous carcinoma (linitis plastica).

may be detected in symptomatic patients with epigastric pain, upper GI bleeding, or other complaints.⁹⁵ Early gastric cancers may also be discovered fortuitously in patients who undergo radiologic or endoscopic examinations for other reasons. Nevertheless, radiologists and endoscopists in the West are unlikely to detect a substantial number of early gastric cancers as long as these examinations are performed predominantly on symptomatic patients.⁹⁵

Advanced Carcinoma

Abdominal Radiographs. Polypoid gastric carcinomas are occasionally recognized on abdominal radiographs by the presence of a soft tissue mass indenting the gastric air shadow (Fig.

32-2A). Primary scirrhous carcinomas can also be recognized by a narrowed, tubular configuration of the gas-filled stomach (Fig. 32-2B). Rarely, mucin-producing scirrhous carcinomas may contain gross areas of calcification that have a stippled, punctate, or sandlike appearance (Fig. 32-3A).^{109–111} When abdominal radiographs are worrisome for gastric carcinoma, barium studies or computed tomography (CT) should be performed for a more definitive diagnosis (Fig. 32-3B). CT is a particularly sensitive technique for demonstrating the calcification in mucin-producing scirrhous tumors (Fig. 32-3C).

Barium Studies. Accurate diagnosis of gastric cancer has always been an important goal of barium studies of the upper

Figure 32-3 Calcified scirrhous carcinoma.

A. Close-up view from an abdominal radiograph shows a large cluster of punctate or sandlike calcifications in the region of the stomach.

B. Barium study in the same patient reveals marked antral narrowing caused by a scirrhous carcinoma of the stomach. Again, note multiple calcifications in this mucin-producing tumor.

C. CT scan shows lobulated thickening of the gastric wall with extensive calcification in another patient with a scirrhous carcinoma. (**C** courtesy Eugene Libson, MD, Jerusalem, Israel.)

GI tract. Unfortunately, single-contrast examinations have an overall sensitivity of only 75% in diagnosing these tumors.¹¹² In one study of 80 patients with gastric carcinoma, however, the lesion was detected on double-contrast examinations in 99% of cases, and malignant tumor was diagnosed or suspected on the basis of the radiographic findings in 96%.¹¹² In the same study, it was found that endoscopy had been recommended because of radiographic findings that were equivocal or suggestive of tumor in only 4% of all patients who underwent double-contrast examinations during this period. Thus, a high sensitivity can be achieved in the diagnosis of gastric carcinoma on double-contrast studies without exposing an inordinate number of patients to unnecessary endoscopy. In another study, missed gastric cancers usually resulted from perceptual errors related to depressed lesions overlooked in the thin barium pool with compression or flow technique.¹¹³

Advanced gastric carcinomas may appear as polypoid, ulcerative, or infiltrating lesions. However, many tumors have mixed morphologic features, so there is considerable overlap in the classification of these lesions. Because scirrhous carcinomas and cardiac carcinomas produce distinctive radiographic findings, these lesions are considered separately in later sections.

Polypoid carcinomas are lobulated or fungating masses that protrude into the lumen (Figs. 32-4 and 32-5). On double-contrast studies, lesions on the dependent or posterior wall are seen as filling defects in the barium pool, whereas lesions on the nondependent or anterior wall are etched in white by a thin layer of barium trapped between the edge of the mass and adjacent mucosa. These tumors often contain one or more irregular areas of ulceration. Occasionally, polypoid antral carcinomas may prolapse through the pylorus into the duodenum,

Figure 32-4 Polypoid gastric carcinoma. A polypoid mass (arrow) is seen on the greater curvature of the stomach.

appearing as mass lesions at the base of the bulb (Fig. 32-6). Rarely, two or more synchronous carcinomas may be present in the stomach (see Fig. 32-5).^{56,57,114}

Ulcerated carcinomas are those in which the bulk of the tumor mass has been replaced by ulceration (Figs. 32-7 and

32-8). Although these lesions are often called *malignant ulcers*, the term is a misnomer, because it is not the ulcer but the surrounding tumor that is malignant. In general, malignant ulcers are characterized en face by an irregular ulcer crater eccentrically located within a ring of malignant tissue.^{115,116} The ulcers may have scalloped, angular, or stellate borders. Discrete tumor nodules are often seen in the adjacent mucosa. Folds converging to the edge of the ulcer may be blunted, nodular, clubbed, or fused as a result of tumor infiltration.^{115,116} On double-contrast studies, malignant ulcers on the nondependent or anterior wall

Figure 32-5 Synchronous gastric carcinomas. Two discrete polypoid masses (arrows) are seen in the stomach as a result of separate, primary gastric carcinomas.

Figure 32-6 Prolapsed antral carcinoma. A polypoid mass (arrow) is seen at the base of the duodenal bulb. This patient had an antral carcinoma that had prolapsed into the duodenum.

Figure 32-7 Ulcerated gastric carcinoma. A. Double-contrast view of the stomach shows a relatively large mass that is etched in white (large arrows) near the lesser curvature of the gastric body. Also note a second curvilinear density (small arrows) secondary to barium coating the rim of an unfilled central ulcer. **B.** Prone compression view shows the mass as a radiolucent filling defect (black arrows) on the anterior wall of the stomach. Note how the central ulcer (white arrows) fills with barium when the patient is in the prone position. The ulcer has a convex inner border and an intraluminal location, demonstrating the features of a Carman-Kirklin meniscus complex. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 32-8 Malignant gastric ulcers. **A.** A meniscoid ulcer (white arrows) is seen on the lesser curvature of the antrum. Note the rind of malignant tumor (black arrows) surrounding the ulcer. **B.** Another malignant ulcer (arrow) is seen on the lesser curvature of the antrum. This ulcer has an intraluminal location. Also note how the folds converging to the ulcer have a nodular, clubbed appearance because of infiltration by tumor. **C.** A third patient has an ulcerated mass on the greater curvature of the antrum. Again, note how the ulcer (white arrow) has an intraluminal location. Also note how the mass itself is etched in white (black arrows).

may be etched in white, so a double ring shadow is observed in the stomach, with the outer ring representing the edge of the tumor and the inner ring representing the edge of the ulcer (see Fig. 32-7A). In such cases, prone compression views should demonstrate filling of the ulcer crater within a discrete tumor mass on the anterior wall (see Fig. 32-7B). A biphasic examination is therefore essential for proper interpretation of these lesions.

When viewed in profile, malignant ulcers usually have an intraluminal location, often within a discrete tumor mass (see Figs. 32-8B and C), whereas benign ulcers project beyond the adjacent contour of the stomach.^{115,116} However, this criterion can be used only for ulcers on or near the lesser or greater curvature. The tumor mass surrounding malignant ulcers usually forms acute angles with the adjacent gastric wall rather than the obtuse, gently sloping angles expected for a benign mound of edema.^{115,116} Clubbed or nodular folds may also be seen radiating to the edge of the ulcer crater or to the edge of the surrounding mass as a result of tumor infiltrating these folds (see Fig. 32-8B).

No sign in GI radiology has generated more confusion than the meniscus sign of a malignant ulcer, which was originally described by Carman in 1921¹¹⁷ and refined by Kirklin in

1934.¹¹⁸ The Carman-Kirklin meniscus complex is caused by a cancer straddling the lesser curvature of the gastric antrum or body, in which the tumor is a broad, flat lesion with central ulceration and elevated margins. Careful compression of the lesion may reveal a meniscoid ulcer with a convex inner border and a concave outer border that does not project beyond the expected gastric contour (see Figs. 32-7B and 32-8A).^{115,116} A radiolucent halo may be seen abutting the meniscus because of apposition of the elevated edges of the tumor on the anterior and posterior walls. Although the Carman-Kirklin meniscus complex is a reliable radiologic sign of malignancy, it can be demonstrated in only a small percentage of all patients with malignant ulcers.

Infiltrating carcinomas are manifested by irregular narrowing of the stomach with nodularity and spiculation of the mucosa (Fig. 32-9). Some infiltrating lesions may have polypoid or ulcerated components. In advanced cases, these lesions may cause gastric outlet obstruction.

Transpyloric spread of antral carcinoma into the duodenum can be demonstrated on barium studies in 5% to 25% of patients.⁷⁰⁻⁷² Duodenal involvement is manifested by mass effect, nodularity, ulceration, or irregular narrowing of the proximal duodenum. Although transpyloric spread of tumor

Figure 32-9 Infiltrating gastric carcinomas. **A.** Irregular narrowing and ulceration are seen in the antrum because of an advanced, infiltrating carcinoma. **B.** In another patient, an infiltrating carcinoma of the proximal stomach causes marked narrowing and spiculation of the upper gastric body.

Figure 32-10 Scirrhou carcinomas of the stomach. **A.** There is marked narrowing of the antrum caused by infiltration of the wall by tumor. **B.** In another patient, there is encasement of the entire stomach by a scirrhou tumor, producing a diffuse linitis plastica appearance.

occurs in a higher percentage of patients with gastric lymphoma, gastric carcinoma is more likely to produce this finding because of its higher incidence.⁷²

Rarely, advanced gastric carcinomas on the greater curvature of the stomach may spread inferiorly via the gastrocolic ligament to the superior border of the transverse colon, resulting in the development of a gastrocolic fistula.⁷³ Although these fistulas may occasionally be shown on an upper GI study, they are more likely to be demonstrated on a barium enema because of the higher pressures generated during this examination.

Scirrhou Carcinoma

Scirrhou gastric carcinomas are traditionally thought to involve the distal half of the stomach, arising near the pylorus and gradually extending upward from the antrum into the body and fundus.^{81,119} These tumors are classically manifested on barium studies by irregular narrowing and rigidity of the stomach,

producing a linitis plastica (“leather bottle”) appearance (Fig. 32-10).^{81,119} In advanced cases, the stomach may be diffusely infiltrated by tumor (see Fig. 32-10B). Other patients may have localized scirrhou tumors confined to the prepyloric region of the antrum, appearing as short, annular lesions with shelflike proximal margins (Fig. 32-11).¹²⁰ With double-contrast technique, however, 20% to 40% of patients with scirrhou tumors are found to have localized lesions involving the gastric fundus or body with sparing of the antrum (Figs. 32-12 and 32-13).^{90,91} Detection of these lesions has presumably improved because of better gaseous distention of the proximal stomach on double-contrast studies. Whatever the explanation, radiologists should be aware that a large percentage of scirrhou carcinomas are localized lesions involving the gastric fundus or body rather than the classic form of linitis plastica involving the distal stomach.

Because of intense fibrosis incited by scirrhou gastric carcinomas, these tumors may convert the stomach into a narrowed,

rigid tube that loses its normal compliance and distensibility. As a result, barium paradoxically may empty from the stomach more rapidly than normal, so all the ingested barium enters the duodenum and proximal small bowel within minutes of starting the examination. This same phenomenon accounts for the early satiety that develops in some patients because the narrowed, rigid stomach is incapable of expanding to accommodate ingested food.

Although scirrhous carcinomas are often manifested by relatively marked gastric narrowing, some tumors cause only mild loss of distensibility. Instead, these lesions may be recognized on double-contrast studies primarily by distortion of the normal surface pattern of the stomach with mucosal nodularity, spiculation, ulceration, or thickened, irregular folds (see

Figure 32-11 Localized scirrhous carcinoma of the distal antrum. A short, annular lesion is seen in the prepyloric region of the antrum. Note how the lesion has an abrupt, shelflike proximal border. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Fig. 32-13).⁹⁰ Thus, some lesions are likely to be missed if the radiologist relies too heavily on gastric narrowing as the major criterion for diagnosing these tumors.

CARCINOMA OF THE CARDIA

Tumors arising at the cardia are notoriously difficult to detect on conventional single-contrast barium studies. Because the overlying rib cage precludes manual palpation or compression of the fundus, even large lesions at the cardia may be obscured by crowded folds or relatively opaque barium, which prevents adequate visualization of this region. With double-contrast technique, however, it is possible to evaluate the normal anatomic landmarks at the cardia and surrounding gastric mucosa for signs of malignancy. As a result, double-contrast barium studies may detect lesions at the cardia that are missed on conventional single-contrast examinations.¹²¹⁻¹²⁵

When viewed en face, the normal cardia often appears on double-contrast studies as a circular elevation containing four or five stellate folds that radiate to a central point at the gastroesophageal junction, also known as the *cardiac rosette* (see Chapter 26).^{122,123} Some lesions at the cardia may be recognized only by subtle nodularity, mass effect, or ulceration in this region with distortion, effacement, or obliteration of the rosette (Fig. 32-14).¹²²⁻¹²⁵ Enlargement or lobulation of the surrounding elevation should also suggest a neoplastic lesion. Finally, an abnormal protrusion at the cardia should persist when additional barium is swallowed, whereas an apparent abnormality at the cardia must be an artifact if it vanishes as the lower esophageal sphincter relaxes and the cardia opens.¹²³

Advanced carcinomas of the gastric cardia or fundus may be polypoid or infiltrating lesions. Polypoid tumors usually appear as lobulated intraluminal masses in the gastric fundus, often containing irregular areas of ulceration.^{125,126} In contrast, infiltrating lesions are manifested by thickened, nodular folds and decreased distensibility of the fundus.^{125,126} Advanced tumors may completely encase the fundus, producing a linitis plastica appearance (Fig. 32-15).

When an equivocal or suspicious lesion is detected in the region of the gastric cardia or fundus, endoscopy should be

Figure 32-12 Localized scirrhous carcinomas of the proximal stomach. A. Irregular narrowing is seen in the gastric fundus and body with sparing of the antrum. **B.** Another patient has a scirrhous carcinoma of the gastric body with sparing of the fundus and antrum. (A from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 32-13 Scirrhous carcinomas of the proximal stomach with thickened folds. **A.** This patient has a localized scirrhous carcinoma of the gastric body. The tumor has caused only mild loss of distensibility. However, there is distortion of the normal surface pattern of the stomach with thickened, irregular folds and mucosal nodularity. **B.** In another patient, a scirrhous carcinoma of the fundus and body is manifested by thickened, lobulated folds without significant narrowing. (**A** from Levine MS, Kong V, Rubesin SE, et al: *Scirrhous carcinoma of the stomach: Radiologic and endoscopic diagnosis. Radiology 175:151–154, 1990.*)

Figure 32-14 Carcinoma of the cardia.

A. The normal anatomic landmarks at the cardia have been obliterated and replaced by a plaque-like lesion (straight arrows) containing a shallow area of ulceration (curved arrow).

B. In another patient, the cardiac rosette has been replaced by a relatively flat mass (straight black arrows) with a central ulcer (white arrow). The tumor extends into the distal esophagus (curved black arrow).

C. In a third patient, there is diffuse nodularity in the fundus with obliteration of the normal cardiac landmarks. Also note involvement of the distal esophagus.

(**B** from Levine MS, Laufer I, Thompson JJ: *Carcinoma of the gastric cardia in young people. AJR 140:69–72, 1983.*)

performed for a more definitive diagnosis. Nevertheless, radiographically demonstrated lesions at the cardia may occasionally be missed at endoscopy.¹²⁷ The barium study should therefore be repeated, despite a negative endoscopic examination, if the initial barium study suggests a malignant lesion. Rarely, some patients with continuing radiologic evidence of

malignancy may require surgery without preoperative histologic confirmation.

Secondary esophageal involvement by advanced lesions may be manifested on barium studies by a polypoid or fungating mass extending from the gastric fundus into the distal esophagus or by thickened folds or irregular narrowing of the distal

Figure 32-15 Secondary achalasia caused by gastric carcinoma. **A.** There is smooth, tapered narrowing of the distal esophagus, producing the classic beaklike appearance of achalasia. **B.** A radiograph of the stomach reveals an advanced scirrhous carcinoma of the gastric fundus that has invaded the distal esophagus. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

esophagus without a discrete lesion (see Fig. 32-14B and C).^{125,126} Esophageal involvement is usually confined to a 4- to 5-cm segment above the gastroesophageal junction but may occasionally extend as far proximally as the aortic arch.¹²⁶ Submucosal spread of tumor can also result in secondary achalasia with tapered, beaklike narrowing of the distal esophagus at or just above the gastroesophageal junction (see Fig. 32-15A and Chapter 24).^{126,128} However, certain morphologic features such as asymmetry, abrupt transitions, and mucosal nodularity or ulceration should suggest an underlying malignancy.¹²⁸ Secondary achalasia should also be suspected when the narrowed segment extends proximally a discrete distance from the gastroesophageal junction.¹²⁹ In such cases, careful radiologic evaluation of the gastric fundus is essential to rule out a carcinoma of the cardia as the cause of these findings.

COMPUTED TOMOGRAPHIC FINDINGS

The widespread availability of multidetector CT (MDCT) scanners has improved the diagnosis of gastric carcinoma on CT because of its ability to create high-quality images in any conceivable view plane (Fig. 32-16). Detection of these lesions requires optimal gastric distention to efface the overlying rugal folds and accentuate areas of asymmetry along the contour of the stomach. Some authors recommend oral administration of a neutral (water-attenuation) contrast agent,¹³⁰⁻¹³³ whereas others recommend the use of an oral effervescent agent (as is used for double-contrast barium studies of the stomach) to optimize gastric distention.^{134,135}

Figure 32-16 MDCT evaluation of gastric carcinoma. **A, B.** Two 3D volume-rendered images in a patient with antral carcinoma show localized wall thickening in the antropylic region of the stomach. **A** shows the lesion (arrow) in a rendering that simulates a left posterior oblique view from an upper GI barium study, whereas **B** shows the lesion (arrowhead) in an orientation that simulates a right anterior oblique view from a barium study. Note the importance of adequately distending the stomach to demonstrate this finding.

Figure 32-17 MDCT of gastric carcinoma correlated with Borrmann classification. Images from four different patients show the various CT appearances of gastric carcinoma (arrows). **A.** Type I polypoid neoplasm. **B.** Type II fungating neoplasm. Also note the presence of multiple hepatic metastases in this patient. **C.** Type III ulcerated neoplasm. **D.** Type IV infiltrating neoplasm.

Optimal MDCT detection of gastric cancer requires that imaging data be collected with the thinnest possible detector configuration (0.6–0.75 mm). Overlapping reconstructions enable the creation of 3D data sets with near-isotropic voxels. Display images are created at 3- to 4-mm intervals and are transmitted directly to the picture archiving and communications system (PACS). Thin slices are simultaneously transmitted to a workstation or thin client server, enabling the creation of 3D images. Clinically useful 3D images displaying the gastric tumor and extragastric extension can be created and selected for the patient's electronic imaging database. The thin sections are not permanently archived, although 3D renderings created from these sections are archived. Intravenous administration of iodinated contrast material is critical, not only for assessing the primary tumor but also for local staging and detection of distant metastases. The images should include the abdomen and pelvis because of the tendency for gastric carcinoma to disseminate widely in the peritoneal cavity.

The Borrmann classification of gastric carcinoma includes four morphologic types of gastric cancer—type I (polypoid), type II (fungating), type III (ulcerated), and type IV (infiltrating). Each of these four types can be visualized on MDCT (Fig. 32-17).¹³⁶ This classification encompasses the spectrum of radiographic findings expected for gastric carcinoma. Although the infiltrating and ulcerated types of cancer are readily recognized as distinct imaging entities,^{137,138} the polypoid and fungating types may be difficult to differentiate. MDCT is not generally used to predict the histology of the tumor, but calcification and/or areas of low attenuation within a thickened gastric wall should suggest the presence of a mucinous carcinoma (Fig. 32-18).¹³⁹

Figure 32-18 Mucinous adenocarcinoma of the stomach. This MDCT scan shows massive thickening of the gastric wall and marked luminal narrowing by an advanced, infiltrating carcinoma. Also note extensive calcification within the tumor. This type of calcification is characteristic of mucinous tumors of the stomach.

Gastric carcinoma is often manifested on MDCT by focal thickening of the gastric wall. In one study, wall thickening greater than 1 cm on CT had a sensitivity of 100% for detecting gastric cancer, but a specificity of less than 50%.¹⁴⁰ Localized wall thickening is a particularly frequent finding in the gastric antrum¹⁴¹ and at the gastroesophageal junction,¹⁴² leading to false-positive diagnoses of tumor. Smooth antral wall thickening (≤ 12 mm), with or without submucosal low attenuation, is

Figure 32-19 False-positive MDCT for gastric carcinoma. **A.** Representative axial MDCT scan shows a focal area of apparent wall thickening (arrow) on the greater curvature of the gastric body that is worrisome for an infiltrating tumor. **B.** A frontal view of the stomach from a subsequent double-contrast upper GI examination shows a normal-appearing stomach without any findings to suggest tumor in the gastric body. In patients with known gastric cancer, the accuracy of MDCT can be improved by using appropriate technique to ensure that the stomach is maximally distended. Nevertheless, it is not always possible to achieve optimal gastric distention on routine abdominal CT.

often seen as a normal finding.¹⁴¹ When a mass is suspected at the gastroesophageal junction, repeat scanning with oral effervescent agent in the prone or left-side down decubitus position should distend the normal stomach and efface the wall, accentuating the presence of tumor.¹⁴¹ If there is still a high index of suspicion for malignant tumor, endoscopic ultrasound (EUS) and biopsy are recommended for a more definitive diagnosis. If, however, the index of suspicion for tumor is low, a double-contrast barium study may be performed to confirm that the stomach is normal. A similar approach may be used to exclude malignant tumor in patients with apparent wall thickening elsewhere in the stomach on MDCT (Fig. 32-19). The symmetry of wall thickening and uniformity of contrast enhancement are also features that help differentiate benign from malignant causes of wall thickening.

Gastric carcinomas often enhance on MDCT after intravenous (IV) administration of iodinated contrast material at rates of 3 mL/s or greater (Fig. 32-20). Some of these tumors may have stratified wall enhancement characterized by brightly enhancing mucosal and serosal layers with less enhancement of the submucosal and muscular layers (Fig. 32-21).^{131,143} Radiologic-pathologic correlation has shown that the degree of enhancement depends on differences in proliferation of cancer cells; more tightly aggregated cells tend to enhance more brightly, whereas more scattered cells result in lower regions of attenuation.¹⁴⁴ MDCT with IV contrast enhancement therefore improves tumor detection and can also be used to produce high-quality CT angiograms that serve as roadmaps for surgeons.¹⁴⁵

DIFFERENTIAL DIAGNOSIS

Early Gastric Cancer

Early gastric cancers may appear on barium studies as depressed (ulcerated), elevated (polypoid), or superficial lesions. Ulcerated cancers must be distinguished from benign gastric ulcers (see earlier, “Early Gastric Cancer”). Occasionally, early gastric

Figure 32-20 Gastric carcinoma with differential wall enhancement on MDCT. This 3D MDCT scan shows wall thickening and hyperdense attenuation in the distal esophagus and region of the gastroesophageal junction (straight arrow) caused by a biopsy-proven adenocarcinoma. The gastric wall is diffusely abnormal, with a thin, uniformly enhancing mucosal layer and a thickened, hypodense submucosal layer (curved arrow), possibly from edema. A focal area of increased mural density (arrowhead) is seen extending from the greater curvature of the distal antrum into the adjacent perigastric fat, suggesting tumor extension.

lymphomas may also appear as ulcerated lesions (see Chapter 33). Polypoid cancers must be distinguished from adenomatous or hyperplastic polyps or other benign or malignant tumors in the stomach. Finally, superficial cancers must be distinguished from a focal area of gastritis or intestinal metaplasia. When early gastric cancer is suspected on barium studies, endoscopy and biopsy are required for a definitive diagnosis.

Figure 32-21 Gastric carcinoma with stratified enhancement patterns on MDCT. **A.** Contrast-enhanced MDCT scan shows a malignant posterior wall ulcer (arrow) with irregular margins. Note decreased enhancement of the adjacent mucosa and a relatively hypodense submucosa. **B, C.** Contrast-enhanced MDCT scans through the proximal stomach in a 35-year-old man show an irregularly thickened gastric wall extending to the gastroesophageal junction secondary to a primary scirrhous carcinoma with linitis plastica. Note the variable enhancement of the mucosa, prominent hyperdensity interspersed throughout the submucosa, and poor margination at the serosa.

Figure 32-22 Metastatic breast cancer involving the stomach. There is antral narrowing with distortion of the normal surface pattern and a nodular, irregular mucosa in this region. A primary scirrhous carcinoma of the stomach could produce identical findings. (From Levine MS, Kong V, Rubesin SE, et al: *Scirrhous carcinoma of the stomach: Radiologic and endoscopic diagnosis*. *Radiology* 175:151–154, 1990.)

Advanced Carcinoma

The major consideration in the differential diagnosis of an ulcerated gastric carcinoma is a benign gastric ulcer with a surrounding mound of edema (see Chapter 29). Polypoid or ulcerated carcinomas must also be distinguished from other polypoid or ulcerated malignant tumors such as lymphoma and malignant GISTs (see Chapter 33). Although the presence of a large, lobulated submucosal mass should favor the diagnosis of lymphoma or a malignant GIST, histologic specimens are required to differentiate these lesions.

Most cases of linitis plastica are caused by gastric carcinoma, but metastatic breast cancer (Fig. 32-22), omental metastases, and non-Hodgkin's lymphoma involving the stomach may

produce similar radiographic findings (see Chapter 33).^{90,146,147} Cone-shaped antral narrowing and deformity may also be caused by scarring from peptic ulcer disease, caustic ingestion, radiation, or a variety of granulomatous diseases, including Crohn's disease, tuberculosis, sarcoidosis, and syphilis (see Chapter 30).¹⁴⁸ Antral narrowing may also occur in older patients who have a so-called senile antrum secondary to gastric atrophy.¹⁴⁹ In general, a smooth antral contour and lack of nodularity, spiculation, or ulceration should suggest benign disease. Rarely, however, these conditions may produce more irregular gastric narrowing, mimicking the appearance of malignant linitis plastica.

Carcinoma of the cardia invading the distal esophagus may be indistinguishable from a primary adenocarcinoma in Barrett's esophagus invading the stomach (see Chapter 23).¹⁵⁰ However, carcinoma of the cardia tends to have a greater degree of gastric involvement in relation to that of the esophagus, whereas primary adenocarcinoma of the esophagus usually has a greater degree of esophageal involvement. Squamous cell carcinoma of the esophagus may also spread distally via submucosal esophageal lymphatics to the gastric cardia or fundus, producing a polypoid lesion in the fundus (see Chapter 23).^{151,152} Occasionally, a conglomerate mass of varices in the fundus may be manifested by a single lobulated lesion that closely resembles a polypoid fundal or cardiac carcinoma (see Chapter 34).^{153,154} Inadequate gaseous distention of the fundus can also mimic the appearance of an infiltrating fundal tumor on double-contrast studies (Fig. 32-23A). However, additional views of the stomach after administration of an additional dose of effervescent agent should show that the fundus is normal in these patients (Fig. 32-23B).

STAGING

CT, EUS, magnetic resonance imaging (MRI), and ¹⁸F-fluorodeoxyglucose (FDG)-positron emission tomography (18-FDG-PET)/CT have important roles in staging patients with

Figure 32-23 Inadequate gaseous distention mimicking a fundal tumor. **A.** Double-contrast radiograph of the stomach shows a possible infiltrating lesion (arrows) on the posterior wall of the fundus. **B.** After administration of additional effervescent agent, there is better distention of the fundus, eliminating the possibility of tumor. Note how the normal cardiac rosette is now visible.

Figure 32-24 Perigastric lymph node metastases from gastric carcinoma. **A.** 3D MDCT scan shows an ulcerated carcinoma of the gastroesophageal junction manifested by an irregular mass with central ulceration (arrow). Enlarged perigastric lymph nodes (asterisks) are present in a periceliac distribution. **B.** In another patient who underwent a previous gastrectomy for gastric carcinoma, an MDCT scan shows peripancreatic lymphadenopathy simulating a carcinoma of the head of the pancreas.

gastric carcinoma. These techniques are therefore discussed separately in the following sections.

Computed Tomography

MDCT is a useful imaging test for staging gastric carcinoma, not only to assess disease spread beyond the gastric wall, but also intraperitoneal seeding and blood-borne metastases. At the same time, MDCT does not always permit accurate depiction of local tumor extension or lymph node involvement. When the diagnosis of gastric carcinoma is already known, MDCT is facilitated by the use of oral effervescent or water-attenuation agents to distend the stomach maximally.

Studies have indicated that MDCT has an increasing role in gastric cancer staging. In a study of 106 patients with gastric carcinoma, T-stage accuracy improved from 77% on axial images to 84% on volumetric images.¹⁵⁵ In another study of 65

patients with gastric cancer, MDCT enabled detection of 96% of advanced gastric cancers and 41% of early gastric cancers, with an overall T-stage accuracy of 85%.¹⁴⁴ By using an effervescent agent to maximize gastric distention and create a 3D volume-rendered “luminal cast” (CT gastroscopy) with multiplanar reformatted images and IV contrast enhancement, other investigators have been able to achieve high accuracy in differentiating T1a from T1b tumors.¹⁵⁶ In one study of 41 patients with gastric cancer, the accuracy of MDCT for serosal invasion was 93%,¹³¹ so MDCT is better for staging patients who have more advanced disease.

Multiple lymphatic channels freely communicate within the gastric wall, providing collateral pathways that facilitate the spread of tumor into regional and distant lymph nodes (Fig. 32-24). Despite numerous technologic advances, MDCT is less useful for detecting lymphatic metastases from gastric

carcinoma, with an overall N-stage accuracy of only 60% to 80%. CT is limited by its inability to identify lymphatic metastases in lymph nodes that are not enlarged. The detection of such metastases could potentially be improved by using monoenergetic, low-keV images derived from dual-energy CT acquisitions.

Gastric carcinoma can metastasize by various routes, including direct extension, spread of tumor via ligamentous and mesenteric structures, intraperitoneal seeding, lymphatic extension, and hematogenous metastases. Each of these modes of spread may be recognized on MDCT. For example, carcinoma of the cardia may extend via the gastrohepatic ligament into the liver; this pathway of spread is particularly well shown on MDCT.¹⁵⁷ Similarly, carcinoma of the gastric antrum or body may extend via the gastrocolic ligament to invade the transverse colon (Fig. 32-25).

In patients with advanced gastric carcinoma, peritoneal carcinomatosis may be manifested on MDCT by characteristic findings, including soft tissue masses and nodules in peritoneal reflections, retraction of the mesenteric root, omental caking, and loculated ascites. Once tumor enters the peritoneal cavity, the tumor cells gravitate to its most dependent portion (the pouch of Douglas in a woman and rectovesical space in a man). The ovaries are another frequent site of intraperitoneal seeding (Fig. 32-26).¹⁵⁸ Krukenberg tumors were originally described as solid ovarian metastases from signet ring cell gastric adenocarcinomas, but the term is now used to refer to any metastases to the ovaries, regardless of the primary source. Despite

widespread knowledge of the varied radiologic appearances of peritoneal carcinomatosis, detection of intraperitoneal metastases by MDCT remains poor.^{159,160} In one study, 18-FDG-PET/CT was found to have an even lower sensitivity than MDCT for detecting these intraperitoneal implants.¹⁶¹

Gastric cancers can also extend through regional lymphatics in a sheetlike fashion into the retroperitoneum, causing ureteral obstruction. Hematogenous metastases from gastric carcinoma are usually found in the liver, but these tumors can metastasize via the blood to a variety of sites.

Endoscopic Ultrasonography

The introduction and dissemination of EUS has substantially improved the accuracy of local staging for gastric cancer.¹⁶² A major advantage of EUS is its ability to visualize the various layers of the gastric wall, perigastric lymph nodes, and relationship of the tumor to the surrounding tissues, enabling determination of the depth of wall invasion and extent of regional lymph node involvement by tumor. Nevertheless, EUS is best performed as a complementary test to cross-sectional imaging studies such as CT for local tumor staging.

Technique. EUS uses high-frequency transducers, typically in the frequency range of 5 to 12 MHz, yielding an effective usable clinical resolution of 200 μ m. There are two basic types of endosonographic equipment available for clinical use—a dedicated EUS endoscope with maneuvering and biopsy capabilities and a standard endoscope in which the EUS equipment is fitted onto catheters and passed through the endoscope. The vast majority of published literature in the United States is based on data obtained with dedicated EUS endoscopes.

EUS requires a trained examiner and is therefore operator dependent.¹⁶³ The examination is usually performed under conscious sedation in an outpatient setting. Dedicated echoendoscopes have a suction capability, so air can be removed from the stomach and deaerated water instilled to allow for better acoustic coupling. An inflatable balloon surrounds the transducer and is filled with deaerated water to increase the surface contact area and improve the imaging window.

With standard technique, EUS visualizes the stomach as a five-layered structure; each individual layer corresponds to a histologically defined layer of the gastric wall (Fig. 32-27).¹⁶⁴ The first hyperechoic layer represents the balloon-mucosal interface, the second hypoechoic layer represents the deep mucosa, the third hyperechoic layer represents the submucosa, the fourth hypoechoic layer represents the muscularis propria, and the fifth hyperechoic layer represents the subserosa and serosa. With proper sonographic technique, EUS may visualize these gastric wall layers and surrounding tissues without air-induced artifacts or interference from gastric contents.

EUS is performed from the transgastric position, allowing visualization of the gastric wall, adjacent lymph nodes, and nearby organs, including the pancreas, spleen, left kidney, and, to a limited degree, the liver. However, EUS is limited by its inability to assess for metastases in the right lobe of the liver or more remote sites because of a limited depth of penetration and imaging window.

If the diagnosis of gastric cancer has not been established before EUS, the examination can be combined with a standard upper endoscopy, so biopsy specimens of the primary tumor can be obtained.¹⁶⁵ As on CT, it may be difficult on EUS to differentiate neoplastic involvement of the stomach from

Figure 32-25 Gastric carcinoma invading the transverse colon via the gastrocolic ligament on sequential axial MDCT scans. **A.** The gastric tumor (T) is manifested by localized wall thickening in the midportion of the stomach. **B.** Nodular densities are present in the gastrocolic ligament (arrow). **C.** Another segment of localized wall thickening (arrowhead) is seen in the transverse colon secondary to invasion by tumor.

Figure 32-26 Gastric carcinoma with peritoneal and ovarian metastases. **A.** MDCT scan shows a linitis plastica type neoplasm infiltrating the gastric wall. Multiple nodules are seen in the gastrocolic ligament (arrowhead) associated with large-volume ascites. **B.** A so-called Sister Mary Joseph nodule is seen to the right of the umbilicus (arrowhead). **C, D.** Left and right adnexal masses (asterisks) are present. The morphology is similar to that of epithelial ovarian neoplasms. Although the term *Krukenberg tumor* classically applies only to solid ovarian masses arising from signet ring cell carcinomas of the stomach, it is now generally used for ovarian metastases from any primary source.

Figure 32-27 Endoscopic ultrasound appearance of the normal gastric wall. Note the typical five-layer wall pattern with a total wall thickness of only several millimeters. (Arrows denote the corresponding wall layers.)

inflammatory processes or fibrosis. EUS also cannot differentiate an early gastric cancer from an adenoma based on echogenicity alone, but evidence of disruption of the normal layers of the gastric wall, local invasion, or suspicious lymph nodes should strongly suggest malignant tumor.

Results. EUS has been shown to be a highly accurate technique for assessing the depth of tumor invasion and presence or absence of regional lymph node involvement in patients with gastric carcinoma.¹⁶⁶⁻¹⁶⁸ In most studies, the overall accuracy of EUS for T staging has ranged from 85% to 88%.¹⁶⁹⁻¹⁷¹ Nevertheless, EUS does have limitations in staging by T classification of gastric cancer because differentiation of subserosal (T2) from serosal (T3) invasion can be extremely difficult. EUS may also overestimate the depth of tumor invasion because of peritumoral inflammation and fibrosis or may underestimate the extent of tumor because of microscopic tumor infiltration of deeper layers of the gastric wall or microscopic nodal metastases.¹⁷² In one study, over staging of the depth of invasion of tumor in the gastric wall led to inappropriate neoadjuvant therapy in 50% of patients.¹⁷³

The finding of a thickened muscularis propria is almost pathognomonic of a malignant gastric tumor, usually gastric carcinoma and, less frequently, lymphoma (Fig. 32-28).^{174,175} EUS is also the most sensitivity imaging technique for detecting perigastric lymph nodes. Unlike CT, in which the detection of abnormal lymph nodes depends entirely on size, the EUS criteria for involved lymph nodes include roundness and hypoechogenicity.^{176,177} Malignant lymph nodes can be detected on EUS with a specificity of almost 90%, but the sensitivity is lower, ranging from 55% to 80%.^{166,170,178,179}

The overall diagnostic accuracy of EUS for determining nodal status (N classification) has ranged from 70% to 90%. A

major limitation of EUS is its inability to detect unenlarged nodes more than 3 cm from the gastric wall. Thus, unless the nodes are enlarged and within range of the transducer, EUS may have limited value in planning the extent of lymphadenectomy. The development of real-time guided, fine-needle aspiration technique increases the accuracy of lymph node assessment because individual lymph nodes can be sampled for tumor.¹⁸⁰

Figure 32-28 Endoscopic ultrasound appearance of linitis plastica. There is marked thickening of the entire gastric wall (arrowheads) with associated thickening of the muscularis propria (arrows).

Nevertheless, some studies have found no significant difference in the overall accuracy of EUS and MDCT for detecting lymph node metastases from gastric cancer,^{181,182} so the ultimate role of EUS remains uncertain.

Other Imaging Modalities. MRI has emerged as another clinically useful imaging test for staging gastric cancer. Diffusion-weighted imaging (DWI) has been shown to be comparable to MDCT for local staging but is more sensitive than MDCT for detecting lymph node metastases.¹⁸³ 18-FDG-PET/CT is also a useful test for whole-body imaging of distant metastases from gastric cancer and for detecting recurrent tumor after treatment.¹⁸⁴ However, 18-FDG-PET/CT has been shown to be inferior to MDCT and diffusion-weighted MRI for detecting regional lymph node metastases (Fig. 32-29).

Summary. The approach to the preoperative staging of patients with gastric carcinoma remains controversial and depends to a major degree on the available imaging, oncologic, and surgical expertise.¹⁶⁵ After the histologic diagnosis of gastric cancer has been made, a cross-sectional imaging study (usually MDCT) is performed to exclude liver metastases or direct extension of tumor into adjacent organs. In patients without metastases or disseminated tumor, EUS can then be performed for local staging of tumor. In such cases, EUS may help select patients with advanced carcinoma for whom neoadjuvant radiation or chemotherapy should be administered before surgery. Patients with T1 to T3 tumors will most likely undergo attempts for curative resection and possibly multimodality therapy, whereas

Figure 32-29 Comparison of MDCT, 18-FDG-PET/CT, and the diffusion-weighted MRI for detecting lymphatic metastasis from esophageal cancer. **A.** Barium study shows an infiltrating adenocarcinoma of the distal esophagus extending distally into the gastroesophageal junction. **B.** 18-FDG-PET/CT image shows marked FDG activity (arrow) in the region of the distal esophageal tumor. **C.** MDCT scan shows an enlarged lymph node (arrow) adjacent to the tumor that was not seen on the PET scan. **D.** Diffusion-weighted MRI scan shows two areas of increased signal secondary to restricted diffusion on this high B value image. Note how the tumor and adjacent lymph node (arrow) are both clearly visible.

patients with T4 tumors may undergo a palliative bypass procedure or endoscopic palliation. Occasional patients with T1 N0 M0 lesions may also undergo endoscopic therapy for attempts at cure if they are not reasonable candidates for surgery.¹⁸⁵ Thus, MDCT and EUS should be considered complementary tests for the preoperative evaluation of patients with gastric carcinoma and selection of optimal treatment regimens.¹⁸⁶

TREATMENT AND PROGNOSIS

Surgery is the only curative form of therapy in patients with gastric carcinoma. Depending on the location of the tumor, a subtotal or total gastrectomy or esophagogastrectomy may be performed. Unfortunately, about 60% of patients who undergo surgery are found to have unresectable tumors.⁸ Nevertheless, a palliative resection or bypass procedure may still be performed on these patients to prevent complications such as bleeding or obstruction. Radiation therapy has also been advocated for palliation of inoperable lesions. Adjuvant chemotherapy has been used in some patients, but the benefits of this treatment remain uncertain. Laser therapy and intraluminal stents have sometimes been used for treatment of patients with obstructing tumors. A detailed discussion of the various operations and postoperative complications is presented in Chapter 35.

Patients with advanced gastric carcinoma have a dismal prognosis, with 5-year survival rates of only 3% to 21%.⁴⁻⁷ In contrast, patients with early gastric cancer have 5-year survival rates of 85% to 100%.^{99,100,107,108,187} Early detection of these lesions is therefore essential for improving patient survival. Thus far, most early gastric cancers have been detected in Japan as a result of mass screening of the adult population in that country. However, some symptomatic patients with gastric cancer in the West are also found to have early lesions. Because it frequently is not possible to distinguish early gastric cancer from advanced carcinoma on preoperative studies, an aggressive surgical approach is justified for all patients with resectable lesions.

Duodenal Carcinoma

Duodenal carcinoma is a rare malignant tumor, accounting for less than 1% of all gastrointestinal neoplasms.¹⁸⁸ Almost all these lesions are located in the second, third, or fourth portions of the duodenum at or distal to the ampulla of Vater.^{189,190} Patients with advanced duodenal cancer usually present with nausea, vomiting, abdominal pain, weight loss, or signs or symptoms of upper GI bleeding. Rarely, however, early duodenal cancer may be detected on double-contrast barium studies or endoscopy in symptomatic patients.¹⁹¹ An increased incidence of duodenal carcinoma has been reported in patients with Gardner's syndrome (see Chapter 61) and celiac disease (see Chapter 43), so some form of radiologic or endoscopic surveillance may be warranted for these patients.^{192,193} Duodenal carcinoma has also been associated with Crohn's disease and neurofibromatosis.¹⁹⁴⁻¹⁹⁶

Duodenal carcinomas usually appear on barium studies as polypoid, ulcerated, or annular lesions at or, more commonly, distal to the ampulla of Vater (Fig. 32-30). Some polypoid carcinomas may arise in preexisting villous tumors (see Chapter 31). Occasionally, duodenal carcinomas have a more proximal location, appearing as ulcerated masses in the proximal descending duodenum or even the duodenal bulb.¹⁹⁷

Figure 32-30 Duodenal carcinoma. An annular, ulcerated lesion (arrows) is seen in the third portion of the duodenum.

Figure 32-31 Early duodenal cancer. Double-contrast spot image of the duodenum shows a sessile, slightly lobulated, 1.3-cm polypoid lesion (arrows) in the duodenal bulb. This was an early cancer that was confined to the mucosa. (From Bradford D, Levine MS, Hoang D, et al: Early duodenal cancer: Detection on double-contrast upper gastrointestinal radiography. *AJR* 174:1564-1566, 2000.)

Nevertheless, the vast majority of duodenal ulcers are benign, so endoscopy should be considered only for lesions that have suspicious radiographic features. Rarely, early duodenal cancers may appear on double-contrast barium studies as small (<2 cm), sessile, polypoid or ulcerated lesions in the duodenum (Fig. 32-31).¹⁹¹

Duodenal carcinoma is usually manifested on CT by a localized area of wall thickening, producing a soft tissue mass (Fig. 32-32). Features such as tumor necrosis and ulceration are readily identified.¹⁹⁸ When CT reveals an exophytic or intramural mass containing central necrosis and ulceration, this combination of findings is reported to have a sensitivity of 100% and accuracy of 86% for the detection of malignant tumor.¹⁹⁹

Figure 32-32 Duodenal carcinoma. **A.** 3D volume-rendered MDCT scan shows narrowing of the postbulbar duodenum by an eccentric soft tissue mass arising in the wall (arrow). **B.** A barium study from the same patient shows an advanced, infiltrating carcinoma of the descending duodenum.

Figure 32-33 Duodenal carcinoma. **A.** Image from 3D MDCT enterography shows an annular lesion (arrowheads) in the third portion of the duodenum. **B.** Barium study confirms presence of this lesion in the distal duodenum.

CT is also useful for differentiating primary duodenal carcinoma from extrinsic tumors involving the duodenum, usually from the pancreas.²⁰⁰ Studies have shown that 3D MDCT is particularly helpful for localizing neoplasms to the duodenum and for accurately defining tumor extent (Fig. 32-33 and 34).²⁰¹ MDCT can also be helpful for detecting periampullary duodenal neoplasms. The differential diagnosis of duodenal wall thickening on CT includes lymphoma, Crohn's disease, hematomas, and duodenitis from a wide variety of causes. However, it is usually possible to suggest the correct diagnosis on the basis of the clinical history and findings on barium studies and CT.

Although ampullary and periampullary carcinomas may be confused with primary pancreatic carcinomas, it is important to distinguish these lesions because ampullary tumors have a much better prognosis. Hypotonic CT duodenography may be useful for differentiating these tumors. The examination is facilitated by placing the patient in the left side down decubitus position after administration of an effervescent agent and 1.0 mg of IV glucagon to obtain scans of the gas-filled duodenal sweep. Ampullary and periampullary lesions may be well demonstrated with this technique (Fig. 32-35).²⁰² CT and MRI scans may also suggest the diagnosis of an ampullary or periampullary tumor when these studies show an ampullary mass, papillary bulging, and irregular narrowing of the distal common bile duct.²⁰³

Figure 32-34 Periampullary duodenal carcinoma. This volume-rendered MDCT scan shows a mass (asterisk) in the periampullary duodenum obstructing the common bile duct with associated dilation of the common bile duct (cbd) and pancreatic duct (pd). MDCT is helpful for determining the cause of periampullary biliary obstruction.

Figure 32-35 Ampullary carcinoma. **A.** Barium study shows a mass (arrow) on the medial aspect of the descending duodenum at the level of the papilla. **B.** CT scan also shows a soft tissue mass (arrow) in this region. **C.** After the administration of additional effervescent agent and 1.0 mg of IV glucagon, a subsequent scan with the patient in the left side down decubitus position clearly delineates this intraluminal mass (arrow) in the descending duodenum.

Miscellaneous Tumors

Metastases

Gastric metastases are found at autopsy in less than 2% of patients who die of carcinoma.¹ Duodenal metastases are even rarer. Nevertheless, metastases to the stomach and duodenum have been encountered more frequently as combined treatment with surgery, radiation, and/or chemotherapy has led to prolonged survival of patients with widespread metastatic disease. Most lesions are hematogenous metastases from malignant melanoma or carcinoma of the breast or lung. Less frequently, the stomach or duodenum may be involved by lymphatic spread of tumor or by direct extension of tumor from neighboring structures or mesenteric reflections such as the gastocolic ligament, transverse mesocolon, and greater omentum. These various forms of spread produce characteristic

radiographic findings that are considered separately in the following sections.

CLINICAL FINDINGS

Most gastroduodenal metastases are discovered unexpectedly at surgery or autopsy.² However, some patients with ulcerated metastases may develop signs or symptoms of upper gastrointestinal (GI) bleeding, such as hematemesis, melena, and guaiac-positive stool.^{3,4} Others may present with epigastric pain, nausea, vomiting, early satiety, anorexia, or weight loss. One or more of these findings are sometimes caused by systemic chemotherapy or the hypercalcemia associated with widespread metastatic disease.⁵ As a result, gastroduodenal metastases may not be suspected, even if symptoms are present.

Most patients with gastroduodenal metastases have a known underlying malignancy. Occasionally, however, metastases to the stomach or duodenum may occur as the initial manifestation of an occult primary tumor.⁴ Certain malignancies such as carcinoma of the breast and kidney can also metastasize to the stomach or duodenum many years after treatment of the original lesion.^{5,6} It is therefore important to obtain a detailed clinical history in these patients.

RADIOGRAPHIC FINDINGS

Hematogenous Metastases

True hematogenous or blood-borne metastases to the stomach or duodenum may be caused by a variety of malignant tumors. Although malignant melanoma has the highest percentage of hematogenous metastases to the GI tract,⁷ breast cancer is such a common disease that it rivals melanoma as the most common cause of metastases to the bowel.⁵ Much less frequently, the stomach or duodenum may be involved by hematogenous metastases from thyroid or testicular carcinoma or from other remote tumors.¹

Hematogenous metastases usually appear on barium studies as one or more discrete submucosal masses in the stomach, duodenum, or small intestine (Fig. 33-1).^{5,8-11} When multiple lesions are present, they tend to be of varying sizes because of periodic showers of tumor emboli into the arterial supply of the bowel.^{8,12} As these submucosal masses outgrow their blood supply, they may undergo central necrosis and ulceration, resulting in the development of classic “bull’s-eye” or “target” lesions (Fig. 33-2).^{8,10-13} In general, bull’s-eye lesions have large central ulcers in relation to the size of the surrounding mass.^{8,12} Superficial fissures may occasionally radiate toward the central ulcer crater, producing a characteristic spoke wheel pattern (see Fig. 33-2B).⁸

Hematogenous metastases to the stomach or duodenum are sometimes manifested by larger, more lobulated masses that can be mistaken radiographically for malignant gastrointestinal

Figure 33-1 Gastric metastases from malignant melanoma. **A.** A discrete submucosal mass (arrow) is seen in the gastric fundus. **B.** In another patient, a large submucosal mass (arrow) is present in the duodenal bulb.

Figure 33-2 Ulcerated gastric metastases from malignant melanoma. **A.** A centrally ulcerated submucosal mass or bull's-eye lesion (arrow) is seen in the gastric body. **B.** In another patient, a prone compression view reveals multiple bull's-eye lesions (black arrows) in the stomach. Superficial fissures are seen radiating from the central ulcer of a metastasis on the lesser curvature, producing a spoke wheel pattern (white arrow).

stromal tumors (GISTs) or even polypoid carcinomas (Fig. 33-3).¹³ Other metastases, particularly those from malignant melanoma, may become necrotic, resulting in the development of giant cavitated lesions. These cavitated metastases can be recognized on barium studies as amorphous collections of barium (usually ranging from 5-15 cm in size) that communicate with the lumen (Fig. 33-4).^{11,14} Computed tomography (CT) is particularly well suited for demonstrating these giant cavitated lesions.¹⁵

Hematogenous metastases to the stomach from breast cancer may produce a linitis plastica or "leather bottle" appearance indistinguishable from that of a primary scirrhous carcinoma of the stomach (Fig. 33-5).^{5,8,9,11} This linitis plastica appearance is caused not by fibrosis (as in patients with scirrhous carcinoma) but by highly cellular infiltrates of metastatic tumor in the gastric wall.⁸ Although the degree of luminal narrowing is variable, these lesions can still be recognized on double-contrast studies by distortion of the normal surface pattern of the

stomach with mucosal nodularity, spiculation, ulceration, or thickened, irregular folds (see Fig. 33-5).¹⁶ Some of these tumors may involve the proximal portion of the stomach with sparing of the antrum (see Fig. 33-5B).¹⁶ The possibility of metastatic disease should therefore be considered in any patient with linitis plastica who has a history of breast carcinoma.

Metastatic disease to the stomach is usually found on CT studies performed as part of the routine work-up of patients with known malignant tumors. Although many extragastric tumors can metastasize to the stomach, careful evaluation of

Figure 33-3 Gastric metastasis from malignant melanoma. There is a large lobulated mass (arrows) on the greater curvature of the stomach. This lesion could be mistaken for a malignant GI stromal tumor or even an adenocarcinoma.

Figure 33-4 Cavitated metastasis from malignant melanoma. A giant cavitated lesion (arrows) is seen on the greater curvature of the stomach. A malignant GI stromal tumor or lymphoma could produce similar findings. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 33-5 Metastatic breast cancer involving the stomach with a linitis plastica appearance. **A.** There is only mild loss of distensibility of the gastric antrum and body, but the mucosa has a nodular, irregular appearance because of infiltration by metastatic tumor. **B.** In another patient, the area of involvement is confined to the proximal half of the stomach. The fundus and body have an irregular contour with thickened, spiculated folds. (From Levine MS, Kong V, Rubesin SE, et al: *Scirrhus carcinoma of the stomach: Radiologic and endoscopic diagnosis. Radiology* 175:151–154, 1990.)

the stomach is particularly important in patients with known malignant melanoma or breast or lung cancer. It has been found that metastatic breast cancer involves the stomach in 5% to 27% of patients, often causing extensive gastric wall thickening (sometimes associated with increased attenuation of the wall after intravenous [IV] contrast enhancement) that simulates the linitis plastica appearance of a scirrhous gastric cancer (Fig. 33-6).^{17,18} In other patients, CT may demonstrate more focal wall thickening (Fig. 33-7). Because these tumors often reside deeply within the gastric wall, it can be difficult to obtain a definitive pathologic diagnosis from endoscopic biopsy specimens. Nevertheless, in the proper clinical setting, CT findings should be highly suggestive of metastatic breast cancer involving the stomach.¹⁹

Hematogenous metastases to the stomach from malignant melanoma, bronchogenic carcinoma, and Kaposi's sarcoma may also be detected on CT.

Lymphatic Spread

Gastric metastases are found at autopsy in 2% to 15% of patients who die of squamous cell carcinoma of the esophagus.²⁰ These metastases are thought to be caused by tumor emboli that seed the gastric cardia or fundus via submucosal esophageal lymphatics extending subdiaphragmatically to paracardiac, lesser curvature, and celiac nodes. Squamous cell metastases to the gastric fundus may appear on barium studies as giant submucosal masses, often containing central areas of ulceration (Fig. 33-8).^{20,21} As a result, these lesions can be mistaken for benign or malignant GISTs or even adenocarcinomas.²² Squamous cell metastases to paracardiac or other lymph nodes in the upper abdomen are sometimes recognized on CT scans as low-attenuation masses relative to skeletal muscle (Fig. 33-9).

The duodenum is occasionally involved by peripancreatic lymphadenopathy from pancreatic carcinoma, lymphoma, or

Figure 33-6 Metastatic breast cancer to the stomach with a linitis plastica appearance on CT. A. Multidetector CT (MDCT) scan of an older woman with metastatic breast carcinoma and early satiety shows marked thickening of the wall of the gastric antrum (arrows). The radiographic findings are indistinguishable from those of a primary scirrhous carcinoma of the stomach. **B.** Barium study in the same patient shows marked narrowing of the antrum, producing a classic linitis plastica appearance.

Figure 33-7 Metastatic breast cancer to the gastric wall on CT. A. MDCT scan of a middle-aged woman with metastatic breast carcinoma shows localized thickening of the greater curvature of the stomach (arrowheads). **B.** ¹⁸F-FDG-PET/CT image in the same patient shows increased activity in the gastric wall (white arrow) and liver (black arrows).

other malignant tumors. In such cases, barium studies may reveal nodular indentations on the medial border of the descending duodenum or widening of the duodenal sweep. However, pancreatic carcinoma, pancreatic pseudocysts, and pancreatitis can produce identical radiographic findings. CT is

extremely helpful for determining the cause of a widened duodenal sweep and for differentiating a pancreatic mass from adjacent lymphadenopathy.

Malignant tumors that metastasize to retroperitoneal lymph nodes near the superior mesenteric root may be manifested on barium studies by extrinsic mass effect, nodular indentations, ulceration, or, in advanced cases, obstruction of the distal duodenum near the ligament of Treitz (Fig. 33-10A).²³ CT is ideally suited for demonstrating retroperitoneal adenopathy as the cause of these abnormalities (Fig. 33-10B). Occasionally, retroperitoneal tumor involving the duodenum may cause delayed

Figure 33-8 Squamous cell metastasis to the gastric cardia. A giant submucosal mass (arrow) in the fundus could be mistaken for a benign or malignant gastrointestinal stromal tumor. (From Glick SN, Teplick SK, Levine MS: *Squamous cell metastases to the gastric cardia*. *Gastrointest Radiol* 10:339–344, 1985.)

Figure 33-9 Metastatic adenopathy from squamous cell carcinoma of the esophagus. A bulky mass of adenopathy is seen in the region of the lesser sac. The low attenuation of the enlarged nodes is characteristic of squamous cell metastases.

Figure 33-10 Duodenal invasion by retroperitoneal adenopathy. **A.** Barium study shows an ulcerated lesion (arrow) at the junction of the third and fourth portions of the duodenum. **B.** CT scan reveals a conglomerate mass of para-aortic adenopathy encasing the distal duodenum with associated ulceration (arrow).

Figure 33-11 Duodenal obstruction by retroperitoneal metastases. Delayed overhead radiograph from an upper gastrointestinal study shows abrupt narrowing of the descending duodenum (arrow) with massive gastric dilation out of proportion to the degree of duodenal dilation. The dilated stomach extends inferiorly into the pelvis. (From Shammash JB, Rubesin SE, Levine MS: Massive gastric distention due to duodenal involvement by retroperitoneal tumors. *Gastrointest Radiol* 17:214–216, 1992.)

gastric emptying and massive gastric dilation out of proportion to the degree of duodenal dilation (Fig. 33-11).²⁴ This disproportionate gastric dilation is probably related to vagal destruction by retroperitoneal tumor, which decreases gastric peristalsis and exacerbates gastric distention.

Direct Invasion

The stomach and duodenum may be directly invaded by malignant tumors arising in neighboring structures such as the esophagus, pancreas, and kidney. The stomach and duodenum may also be involved by direct extension of colonic carcinoma along mesenteric reflections (including the gastrocolic ligament and transverse mesocolon) or by contiguous spread of tumor from the greater omentum. Because the radiographic findings depend on the pathways of spread, the various primary malignant tumors are discussed separately in the following sections.

Esophageal Carcinoma. In contrast to squamous cell carcinomas of the esophagus, adenocarcinomas arising in Barrett's mucosa have a marked tendency to invade the gastric cardia or fundus.^{25,26} Gastric involvement may be manifested on barium studies by a large polypoid or ulcerated mass in the gastric fundus. In other cases, however, double-contrast views of the fundus may reveal more subtle findings, with distortion or obliteration of the normal anatomic landmarks at the cardia (the cardiac rosette) and irregular areas of ulceration or nodularity (see Chapter 23).²⁵ It is sometimes difficult to determine whether these tumors at the gastroesophageal junction have arisen in the esophagus or stomach. In general, however, esophageal adenocarcinomas have a disproportionate degree of

esophageal involvement in relation to that of the stomach, whereas gastric or cardiac carcinomas have a greater degree of fundal involvement.

Pancreatic Carcinoma. The radiographic manifestations of gastroduodenal involvement by pancreatic carcinoma depend on whether the underlying tumor is located in the head, body, or tail of the pancreas. Carcinoma of the pancreatic head may cause widening of the duodenal sweep or extrinsic compression of the medial border of the descending duodenum or greater curvature of the gastric antrum, whereas carcinoma of the pancreatic body or tail may cause extrinsic compression of the posterior wall of the gastric fundus and body or the superior border of the distal duodenum near the ligament of Treitz.²⁷ Invasion of the stomach or duodenum may be manifested on barium studies by spiculated mucosal folds, nodularity, mass effect, ulceration, obstruction or, rarely, fistula formation (Figs. 33-12 to 33-14).²⁷

Many patients with suspected pancreatic neoplasms undergo CT as the initial diagnostic examination. Although CT is of limited value in predicting minimal duodenal invasion by pancreatic carcinoma, distention of the duodenum with gas or water can facilitate detection of subtle findings of invasion. CT is of greater value in determining the cause of an abnormal retrogastric impression because it can differentiate pancreatic carcinoma from pancreatic pseudocysts (Fig. 33-15), retrogastric varices, or other abnormalities in the retroperitoneum compressing the stomach.^{28,29}

Renal Cell Carcinoma. Direct invasion of the duodenum by right-sided renal cell carcinoma may be manifested on barium studies by mass effect, nodularity, or ulceration of the right posterolateral border of the descending duodenum. However, renal cell carcinoma tends not to elicit a desmoplastic response in the wall of the bowel, so duodenal involvement is sometimes manifested by a polypoid intraluminal mass, mimicking the appearance of a primary duodenal carcinoma.^{6,8} In patients with advanced renal cell carcinoma, CT is useful for determining the extent of tumor and its proximity to the duodenum. When a contiguous lesion is identified, however, CT is not reliable for determining whether tumor is invading the duodenum.

Colonic Carcinoma. Colonic carcinoma may involve the stomach or duodenum by direct extension along mesenteric reflections such as the gastrocolic ligament or transverse mesocolon. The gastrocolic ligament is the proximal portion of the greater omentum that extends superiorly from the anterosuperior border of the transverse colon to the greater curvature of the stomach (Fig. 33-16). Because of this anatomic relationship, carcinoma of the transverse colon may invade the stomach via the gastrocolic ligament, producing mass effect, nodularity, and spiculated tethered folds on the greater curvature of the gastric antrum or body.⁸ In other patients, carcinoma of the ascending colon or hepatic flexure may invade the duodenum via the lateral reflection of the transverse mesocolon, producing mass effect, nodularity, ulceration, or spiculated folds on the lateral border of the descending duodenum (Fig. 33-17A).^{30,31} In such cases, a barium enema examination may show the underlying colonic neoplasm responsible for these findings, and CT may show the mode of spread to the stomach or duodenum (Fig. 33-17B).

Figure 33-12 Duodenal invasion by pancreatic carcinoma. **A.** Irregular ulceration (arrows) is seen on the medial border of the descending duodenum, secondary to invasion by pancreatic carcinoma. **B.** In another patient, there is narrowing and obstruction of the descending duodenum (arrow) by an advanced pancreatic carcinoma. This patient has gastric outlet obstruction with a dilated, fluid-filled stomach diluting the ingested barium. (**A** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 33-13 Gastric invasion by pancreatic carcinoma. **A.** Barium study shows a focal area of mass effect (arrow) on the greater curvature of the stomach. **B.** CT scan reveals an advanced pancreatic carcinoma invading the stomach.

Carcinoma of the transverse colon invading the stomach or carcinoma of the hepatic flexure invading the duodenum may occasionally lead to the development of a gastrocolic or duodenocolic fistula (see Chapter 34).³² In today's pill-oriented society, however, most such fistulas are caused by aspirin-induced or other nonsteroidal anti-inflammatory drug (NSAID)-induced greater curvature ulcers that penetrate via the gastrocolic ligament into the transverse colon (see Chapter 29).

Gallbladder Carcinoma. Advanced carcinoma of the gallbladder may directly invade adjacent structures such as the liver, duodenum, and hepatic flexure of the colon. Duodenal

involvement by tumor has been reported in about 20% of patients.³³ CT is particularly useful for showing gastric and duodenal invasion by tumor (Fig. 33-18).

Omental Metastases. Bulky metastatic deposits in the greater omentum, or so-called omental cakes, usually result from widespread intraperitoneal dissemination of ovarian carcinoma or, less frequently, cervical, uterine, bladder, gastric, colonic, pancreatic, or breast carcinoma.³⁴ These omental deposits may spread superiorly to the stomach via the proximal portion of the greater omentum, also known as the gastrocolic ligament (see Fig. 33-16). Gastric involvement by omental metastases is characterized on barium studies by mass effect, nodularity,

flattening, or spiculated, tethered folds on the greater curvature of the gastric antrum or body (Fig. 33-19A).³⁵ These changes reflect serosal involvement by tumor and a desmoplastic response that occurs along the insertion of the gastrocolic ligament on the greater curvature. In advanced cases, there may be circumferential narrowing of the gastric antrum resulting from encasement by metastatic tumor.³⁵

Carcinoma of the transverse colon invading the stomach via the gastrocolic ligament may produce identical radiographic findings (see earlier, "Colonic Carcinoma").⁸ In such cases, however, a barium enema examination should demonstrate the primary colonic carcinoma responsible for these findings. In contrast, patients with omental metastases involving the stomach almost always have associated colonic involvement by omental tumor, with mass effect, nodularity, and spiculated folds on the superior border of the transverse colon (Fig. 33-19B) or, in advanced cases, circumferential narrowing of the bowel.³⁶ In our experience, gastric involvement by omental metastases is far more common than gastric invasion by colonic carcinoma via the gastrocolic ligament.

When gastric involvement by omental metastases is suspected on barium studies, CT is extremely helpful for

Figure 33-14 Gastric invasion by pancreatic carcinoma. There is extrinsic mass effect (black arrows) on the posterior wall of the gastric fundus from an adjacent carcinoma of the pancreatic tail. The spiculated contour of the stomach (white arrows) indicates gastric invasion by tumor. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 33-15 Gastric involvement by a pancreatic pseudocyst. **A.** Barium study shows smooth extrinsic compression (arrows) of the posterior wall of the gastric fundus. **B.** CT scan reveals a large pancreatic pseudocyst (arrow) as the cause of this finding.

delineating the extent of metastatic tumor. Although barium studies provide indirect evidence of omental tumor, CT can reveal omental masses as small as 1 cm in diameter.³⁷ More extensive omental metastases may be manifested on CT by a spectrum of findings, ranging from a lacy reticular appearance to bulky masses.³⁷ Non-neoplastic processes involving the omentum (notably tuberculous peritonitis) can simulate omental tumor. When the greater omentum is diffusely infiltrated by tumor, an omental cake may displace the colon or small bowel from the anterior abdominal wall (Fig. 33-19C).^{34,38} Unless the lumen of the bowel is distended with contrast medium or gas, however, it is difficult to determine whether tumor is invading the stomach or transverse colon.

DIFFERENTIAL DIAGNOSIS

Hematogenous metastases that appear as small nodular lesions in the stomach or duodenum may be difficult to differentiate

Figure 33-16 Sagittal diagram shows the mesenteric attachments of the stomach, small bowel, and colon. Because the proximal portion of the greater omentum (the gastrocolic ligament) inserts along the greater curvature of the stomach, contiguous spread of tumor from the transverse colon or greater omentum primarily affects this region. (From Rubesin SE, Levine MS: *Omental cakes: colonic involvement by omental metastases*. *Radiology* 154:593–596, 1985.)

Figure 33-17 Duodenal invasion by colonic carcinoma. **A.** A large area of mass effect is seen on the lateral border of the descending duodenum with associated ulceration (*white arrow*). This finding was caused by carcinoma of the hepatic flexure invading the duodenum. **B.** In another patient, CT scan shows invasion of the duodenum by recurrent carcinoma arising from the region of an ileotransverse colonic anastomosis (A). A heterogeneous mass (M) is seen invading the duodenum (D) and right kidney (K). Contrast medium is present in the bowel (*black arrow*) adjacent to the anastomosis.

Figure 33-18 Gallbladder carcinoma invading the stomach and duodenum. **A.** Barium study shows narrowing and ulceration of the postbulbar duodenum (*black arrow*) and distortion of the distal gastric antrum (*white arrow*) because of invasion by tumor. **B.** CT scan in the same patient shows an advanced carcinoma of the gallbladder (M) directly encasing and narrowing the descending duodenum (*arrowhead*). Also note tumor invading the distal stomach and infiltrating the peritoneal cavity.

on barium studies from multiple hyperplastic or adenomatous polyps. Metastases that have a more typical submucosal appearance can be mistaken for benign intramural lesions such as GISTs, lipomas, or ectopic pancreatic rests. However, these benign mesenchymal tumors tend to occur as solitary lesions, whereas metastases are usually multiple. Centrally ulcerated bull's-eye lesions may be caused not only by hematogenous metastases but also by lymphoma, Kaposi's sarcoma, or carcinoid tumors. Occasionally, varioliform erosions surrounded by unusually prominent mounds of edema can be mistaken for bull's-eye lesions. However, varioliform erosions are rarely larger than 1 cm, and the central barium collections are considerably smaller than those seen in ulcerated submucosal masses.

Giant cavitated lesions in the stomach and duodenum may be caused not only by metastatic disease (particularly malignant melanoma) but also by lymphoma or malignant GISTs. However, malignant GISTs tend to occur as solitary lesions, so the presence of multiple cavitated masses in the stomach, duodenum, or small bowel should favor a diagnosis of metastatic disease or lymphoma.

The linitis plastica appearance caused by metastatic breast cancer may be indistinguishable on barium studies from that of a primary scirrhous carcinoma of the stomach. Circumferential gastric involvement by pancreatitis, pancreatic carcinoma, colonic carcinoma, omental metastases, lymphoma, or Crohn's disease and scarring from various types of severe gastritis may

Figure 33-19 Gastric and colonic involvement by omental metastases from ovarian carcinoma. **A.** Upper GI study shows spiculated folds and nodularity on the greater curvature of the gastric antrum and body as a result of direct extension of tumor from the greater omentum. **B.** Barium enema shows spiculation and tethering of the superior border of the transverse colon (arrows) as a result of simultaneous colonic involvement by omental tumor. **C.** In another patient, CT scan reveals ascites with a bulky omental cake separating the small bowel from the anterior abdominal wall. (**C** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

produce similar findings. Nevertheless, the possibility of metastatic disease should be considered when a linitis plastica appearance is detected in patients who were previously treated for breast cancer.

Direct invasion of the stomach and duodenum by metastatic tumor may be simulated by various benign and malignant conditions in the upper abdomen. Compression or displacement of the greater curvature or posterior wall of the stomach or of the medial border of the descending duodenum may be caused not only by pancreatic carcinoma but also by pancreatitis, pancreatic pseudocysts (see Fig. 33-15), peripancreatic lymphadenopathy, abdominal aortic aneurysms, or other retroperitoneal processes. Various signs of bowel wall invasion (e.g., mass effect, nodularity, and spiculated, tethered folds) may also result from a nonspecific desmoplastic response to inflammatory conditions involving the stomach. Thus, pancreatitis may produce changes on the greater curvature that are impossible to distinguish from pancreatic or colonic carcinoma or omental metastases involving the stomach. Other imaging techniques such as CT are usually helpful for differentiating these conditions.

Lymphoma

Lymphoma involves the stomach more frequently than any other portion of the gastrointestinal tract. Gastric lymphoma accounts for 50% of all GI lymphomas, 25% of all extranodal lymphomas, and 3% to 5% of all malignant tumors in the

stomach.³⁹⁻⁴¹ More than 50% of patients with gastric lymphoma have localized disease that is confined to the stomach and regional lymph nodes (primary gastric lymphoma); the remainder have generalized lymphoma with associated gastric involvement (secondary gastric lymphoma).⁴¹ When it occurs, duodenal lymphoma usually results from contiguous transpyloric spread of lymphoma from the stomach. Because of its rarity, duodenal lymphoma is considered separately in a later section.

The vast majority of gastric lymphomas are non-Hodgkin's lymphomas of B-cell origin.⁴² There is considerable evidence that these lymphomas arise from mucosa-associated lymphoid tissue (MALT) occurring in patients with chronic *Helicobacter pylori* gastritis.⁴³ It has therefore been postulated that most primary non-Hodgkin's gastric lymphomas originate as low-grade MALT lymphomas, which, if untreated, eventually progress to more high-grade lymphomas. In the past, low-grade proliferation of lymphoid tissue in the stomach was sometimes known as pseudolymphoma.⁴⁴ However, these pseudolymphomas are currently thought to represent monoclonal B-cell proliferations or true B-cell MALT lymphomas.^{45,46} As a result, the term *pseudolymphoma* has largely been abandoned.

Because the gross pathologic findings are nonspecific, gastric lymphoma is often difficult to differentiate from gastric carcinoma on radiologic or endoscopic examination. However, gastric lymphoma has a much better prognosis than gastric carcinoma, with overall 5-year survival rates of 50% to 60%.⁴⁷⁻⁴⁹

Thus, failure to obtain biopsy specimens from an advanced lesion that is assumed to be inoperable gastric cancer may deprive the patient of the opportunity for cure or long-term palliation. Proper staging of the tumor is also important, so a rational decision can be made about treatment options such as surgery, radiation, and chemotherapy.

PATHOLOGY

The vast majority of gastric lymphomas are non-Hodgkin's lymphomas. Only rarely are these patients found to have Hodgkin's lymphoma. Because of confusion with prior classification systems, pathologists at the National Cancer Institute have developed a working formulation that recognizes three prognostic categories of non-Hodgkin's lymphoma—low grade, intermediate grade, and high grade.⁵⁰ Advanced lesions are usually classified as high-grade lymphomas of the large cell or immunoblastic type.⁵¹

The literature suggests that most primary non-Hodgkin's gastric lymphomas are low-grade B-cell lymphomas that arise from MALT.^{52,53} These lesions have been classified as marginal zone B-cell MALT lymphomas by the International Lymphoma Study Group.⁵⁴ Paradoxically, these low-grade MALT lymphomas often occur in the stomach, which normally contains no organized lymphoid tissue.^{52,53} However, it has been well documented that chronic *H. pylori* gastritis leads to the acquisition of lymphoid follicles and aggregates in the lamina propria (MALT)⁵⁵⁻⁵⁷ and the subsequent development of low-grade, B-cell MALT lymphomas.^{52,53,58} Studies have also suggested that almost all patients with low-grade MALT lymphomas have particular strains of *H. pylori* containing the cytotoxin-associated gene A (*cagA*),⁵⁹ so these strains may have an important role in the pathogenesis of gastric MALT lymphoma.

Gastric MALT lymphomas are manifested pathologically by infiltration of the epithelium with small centrocyte-like cells, giving rise to the lymphoepithelial lesions characteristic of these tumors.⁵⁴ In various series, MALT lymphomas have been found to constitute as many as 50% to 72% of all primary gastric lymphomas,^{60,61} so this is a more common tumor than was previously recognized.

It has been shown that regions of low-grade MALT lymphoma are present on histopathologic examination in approximately 30% of patients with high-grade gastric lymphoma.^{60,62} The findings from these studies support the concept that most non-Hodgkin's gastric lymphomas originate as low-grade gastric MALT lymphomas, which subsequently undergo transformation to intermediate- or high-grade lymphomas. These low-grade MALT lymphomas could therefore be considered to be a form of early gastric lymphoma, defined as lymphoma limited to the mucosa or submucosa of the gastric wall, regardless of the presence or absence of lymph node metastases.⁴⁶

Primary gastric lymphoma is usually confined to the stomach or regional lymph nodes at the time of diagnosis. In the Ann Arbor staging system,⁴¹ stage IE lesions involve the gastric wall, stage IIE lesions involve regional lymph nodes in the abdomen, stage III lesions involve lymph nodes above and below the diaphragm, and stage IV lesions are widely disseminated lymphomas that involve extra-abdominal lymph nodes and the omentum, mesentery, peritoneum, liver, spleen, lungs, or brain. The major factors affecting survival of patients with primary gastric lymphoma are the depth of invasion of the gastric wall and presence or absence of nodal disease.

CLINICAL FINDINGS

Gastric lymphoma occurs more frequently in men than in women, and the average age at the time of diagnosis is 55 to 60 years.⁶³ Patients with advanced lesions may present with abdominal pain, nausea, vomiting, anorexia, weight loss, a palpable epigastric mass, or signs of upper GI bleeding.⁶³ Occasionally, these patients may develop an acute abdomen because of spontaneous perforation of an ulcerated gastric lymphoma or perforation complicating systemic chemotherapy.⁶⁴ Patients with generalized lymphoma may also present with a fever or other signs of systemic disease. Whether or not affected individuals have primary gastric lymphoma or generalized lymphoma with gastric involvement, these lesions are often quite extensive in relation to the clinical presentation. Gastric lymphoma should therefore be suspected when a relatively advanced lesion in the stomach is associated with a paucity of clinical complaints.

In contrast to patients with early gastric cancer, who are usually asymptomatic (see Chapter 32), patients with early gastric lymphoma (particularly those with low-grade B-cell MALT lymphoma) may present with epigastric pain, dyspepsia, bloating, nausea, and/or vomiting.⁶⁵⁻⁶⁷ The symptoms at presentation are therefore indistinguishable from those caused by gastric or duodenal ulcers, gastritis, or duodenitis. Some patients may have underlying *H. pylori* gastritis as the cause of their symptoms. Whatever the explanation, the development of symptoms provides an opportunity to diagnose these low-grade gastric MALT lymphomas before they progress to more advanced lesions.

ENDOSCOPIC FINDINGS

Low-grade gastric MALT lymphomas may be manifested at endoscopy by shallow ulcers, polypoid lesions, or erythematous, nodular mucosa.^{65,67} In contrast, high-grade lymphomas may be manifested by enlarged rugal folds, infiltrative masses, or nodular, polypoid, or ulcerated lesions in the stomach.^{68,69} Occasionally, endoscopy may reveal a characteristic volcano crater, with a discrete ulcer surrounded by a narrow ridge of tumor.⁶⁹ Depending on the endoscopic findings, gastric lymphomas may be difficult to differentiate from carcinomas, benign GISTs, metastatic tumor, Ménétrier's disease, hypertrophic gastritis, or even benign gastric ulcers. Endoscopic biopsy specimens are therefore required for a definitive diagnosis. Superficial biopsy specimens may be nondiagnostic because lymphomas often infiltrate the gastric wall beneath an intact mucosa. Whenever possible, multiple brushings and biopsy specimens should therefore be obtained from ulcerated or polypoid areas in which tumor is more likely to be present. Deep biopsy specimens should also be obtained when the overlying mucosa appears normal. With adequate cytologic and biopsy specimens, endoscopy has a reported sensitivity of 85% to 95% in diagnosing gastric lymphoma.⁷⁰⁻⁷²

TREATMENT AND PROGNOSIS

When the diagnosis of gastric lymphoma has been established, proper staging of the tumor is needed to determine the appropriate treatment and assess prognosis. Additional diagnostic examinations include chest radiography, chest and abdominal CT scans, and ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG)-labeled

Figure 33-20 Low-grade mucosa-associated lymphoid tissue (MALT) lymphoma with regression after treatment. **A.** Initial double-contrast study shows confluent, varying-sized nodules in the gastric body caused by a low-grade B-cell MALT lymphoma. **B.** After treatment with chemotherapy, a repeat study 2 years later shows marked regression of tumor in this patient. (**A** from Yoo CC, Levine MS, Furth EE, et al: *Gastric mucosa-associated lymphoid tissue lymphoma: Radiographic findings in six patients.* *Radiology* 208:239–243, 1998.)

PET/CT imaging. When CT and ^{18}F -FDG-PET/CT scans are normal, routine staging laparotomy is probably unnecessary.⁷³

Many investigators think that the best treatment for early or localized gastric lymphoma with or without regional lymph node involvement (stage IE or IIE lesions) is a subtotal gastrectomy with postoperative radiation or chemotherapy.*

Although the role of systemic chemotherapy for localized gastric lymphoma remains controversial, advanced gastric lymphoma (stage III or IV lesions) is sometimes treated by radiation therapy, chemotherapy, or both, without a gastric resection.⁶³ Massive upper GI bleeding or even gastric perforation may occur as a complication of systemic chemotherapy, resulting in treatment failures.⁶⁴

In contrast to high-grade gastric lymphomas, low-grade MALT lymphomas can often be treated successfully by combination therapy with proton pump inhibitors. In various studies, complete or partial regression of tumor has been reported in 60% to 80% of patients after eradication of *H. pylori* from the stomach.^{66,76} One theory is that *H. pylori* evokes an immunologic response that stimulates growth of the tumor. Whatever the explanation, eradication of *H. pylori* from the stomach with antibiotics appears to be a viable alternative to surgery, radiation, or chemotherapy as a first-line treatment for low-grade gastric MALT lymphomas.

Long-term survival depends primarily on the stage of the tumor at the time of diagnosis. In various studies, reported 5-year survival rates have ranged from 62% to 90% for stage IE lesions and from 29% to 50% for stage IIE lesions, but substantially lower rates are reported for stages III and IV lesions.^{47,49,72,77} Patients with low-grade gastric MALT lymphomas have a much better prognosis than patients with high-grade lymphomas; low-grade lymphomas are associated with 5-year survival rates

of 75% to 91%,^{60,67} whereas high-grade MALT lymphomas are associated with 5-year survival rates of less than 60%.⁶⁷

After treatment, some patients may develop recurrent gastric lymphoma, whereas others are found to have recurrent tumor in distal nodal groups without evidence of gastric disease. Patients with recurrent lymphoma almost always become symptomatic within 2 years of treatment, so the prognosis is excellent for patients who remain asymptomatic for more than 5 years.⁷⁸ Gastric lymphoma has a better prognosis than gastric carcinoma because of its inherent growth characteristics and its tendency to remain in the gastric wall for prolonged periods.

RADIOGRAPHIC FINDINGS

Low-Grade Mucosa-Associated Lymphoid Tissue Lymphoma

Low-grade gastric MALT lymphomas may be manifested on double-contrast studies by variably sized, rounded, often confluent nodules involving a focal or, less frequently, diffuse segment of the stomach (Fig. 33-20).⁷⁹⁻⁸² Other MALT lymphomas may appear as small polypoid or ulcerated lesions, as shallow, irregular ulcers with nodular surrounding mucosa, or as focally distorted, enlarged rugal folds.⁸⁰⁻⁸² These early lymphomas may be indistinguishable from early gastric cancer on the basis of the radiographic findings.

Endoscopic biopsy specimens should be obtained for a definitive diagnosis when low-grade MALT lymphomas are suspected on the basis of the radiographic findings. Although some patients may be found to have other conditions such as *H. pylori* gastritis without evidence of tumor (see later, “Differential Diagnosis”), it seems reasonable to accept a certain percentage of false-positive diagnoses because of the importance of detecting gastric MALT lymphomas at an early, curable stage.

*See references 41, 49, 63, 72, 74, and 75.

Advanced Gastric Lymphoma

Advanced gastric lymphomas have an average diameter of 10 cm or more at the time of diagnosis.⁴⁰ Although the entire stomach may be infiltrated by tumor, most cases involve the antrum and body.⁸³ Depending on the gross pathologic features, gastric lymphomas may be classified radiographically as infiltrative, ulcerative, polypoid, or nodular lesions.^{40,83-86} There is considerable overlap between these types, however, with many lesions having combined radiographic features.

Infiltrative gastric lymphomas are characterized by focal or diffuse enlargement of rugal folds caused by submucosal spread of tumor (Fig. 33-21A).^{40,83-86} The folds can be massively enlarged and often have a distorted, nodular contour, so they

can be mistaken for polypoid masses. Even with extensive lymphomatous infiltration, the stomach typically remains pliable and distensible because of the absence of associated fibrosis.^{40,83} However, some non-Hodgkin's lymphomas may produce a linitis plastica appearance indistinguishable from that of a primary scirrhous carcinoma of the stomach.⁸⁷ These lesions are characterized by varying degrees of narrowing of the gastric antrum, body, or fundus with nodularity, ulceration, and thickened or effaced mucosal folds (Fig. 33-21B). This linitis plastica appearance is caused by dense infiltrates of lymphomatous tissue in the gastric wall without associated fibrosis.⁸⁷ The histopathologic findings are therefore similar to those of metastatic breast cancer in which gastric narrowing is caused by highly cellular deposits of metastatic tumor.⁸⁸ Conversely,

Figure 33-21 Various forms of gastric lymphoma. **A.** Diffusely thickened, irregular folds are present in the stomach because of lymphomatous infiltration of the gastric wall. **B.** This patient has linitis plastica, manifested by focal narrowing of the gastric body with nodularity and sacculation of the adjacent greater curvature. **C.** Several discrete ulcers (arrows) and thickened, lobulated folds are seen in the gastric fundus and body. **D.** Two separate polypoid masses (white arrows) are seen on the lesser and greater curvature of the stomach. The greater curvature mass is ulcerated (black arrow). **E.** Two centrally ulcerated submucosal masses, or bull's-eye lesions (arrows), are present in the gastric antrum. (**A** and **E** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992; **B** from Levine MS, Pantongrag-Brown L, Aguilera NS, et al: *Non-Hodgkin lymphoma of the stomach: A cause of linitis plastica*. *Radiology* 201:375-378, 1996; **D** courtesy Duane G. Mezwa, MD, Royal Oak, MI.)

Hodgkin's lymphoma involving the stomach produces a linitis plastica appearance by inciting a marked desmoplastic response similar to that of a primary scirrhous carcinoma.⁸⁹

Ulcerative lymphomas are characterized by one or more ulcerated lesions in the stomach (Fig. 33-21C).^{40,83-86} Occasionally, the ulcers may be surrounded by a smooth mound of tumor or symmetric radiating folds, mimicking the appearance of benign gastric ulcers.⁸⁴ Usually, however, these ulcers have an irregular configuration associated with nodular surrounding mucosa or thickened, irregular folds resulting from lymphomatous infiltration of the gastric wall (see Fig. 33-21C).^{40,84-86} Other gastric lymphomas may appear as giant cavitated lesions as a result of necrosis and excavation of the tumor.^{84,86}

Polypoid gastric lymphomas are characterized by one or more lobulated intraluminal masses indistinguishable from those of polypoid carcinomas (Fig. 33-21D).^{40,83,84} Finally, the nodular form of gastric lymphoma is characterized by multiple submucosal nodules or masses, ranging from several millimeters to several centimeters in size.^{84,85} These submucosal masses often ulcerate, producing typical bull's-eye or target lesions (Fig. 33-21E).⁹⁰ In such cases, the central barium collections tend to be relatively large in relation to the surrounding elevations. Other patients may have multiple polyps indistinguishable from those associated with the various polyposis syndromes.

About 10% of patients with gastric lymphoma have contiguous transcardiac spread of tumor from the gastric fundus into the distal esophagus.⁹¹ Esophageal involvement is usually manifested by thickened, irregular folds, luminal narrowing or, less frequently, a polypoid mass in the distal esophagus.⁹¹ Because

adenocarcinoma is a much more common malignant tumor in the stomach, these findings are more likely to result from distal esophageal involvement by a fundal or cardiac carcinoma.

Gastric lymphoma may also extend into the duodenum by contiguous transpyloric spread. In various series, 30% to 40% of patients with gastric lymphoma have associated duodenal involvement on barium studies (see later, "Duodenal Lymphoma").^{91,92} Because gastric carcinoma invades the duodenum in only 5% to 25% of patients,^{92,93} it has been suggested that concomitant involvement of the stomach and duodenum by tumor should favor a diagnosis of lymphoma. However, adenocarcinoma is so much more common than lymphoma that it is still the most likely diagnosis on empirical grounds.⁹²

Patients with advanced gastric lymphoma are sometimes treated exclusively with radiation or chemotherapy. Follow-up barium studies or CT scans are useful in these patients for documenting the response to treatment and for evaluating GI bleeding or other symptoms that develop after the initiation of radiation or chemotherapy (Figs. 33-22 and 33-23).^{94,95} Follow-up studies may show dramatic regression or resolution of the lymphomatous lesions, often associated with narrowing and deformity of the stomach at the site of the previous lesion as a result of residual scarring and fibrosis.⁹⁵ In other patients, chemotherapy may lead to marked regression of ulcerated mass lesions with the development of benign-appearing ulcers or ulcer scars at the site of the previous lesions (see Fig. 33-22C).⁹⁴ Chemotherapy may also lead to further ulceration, a confined perforation or, rarely, free perforation of these lymphomatous lesions with the development of massive upper GI bleeding or peritonitis (see Figs. 33-22B and 33-23B).⁹⁴

Figure 33-22 Response of gastric lymphoma to chemotherapy. **A.** Initial barium study shows thickened, irregular folds on the greater curvature of the gastric body caused by lymphoma. **B.** After treatment with chemotherapy, follow-up study 6 months later shows regression of the lymphoma with a large area of cavitation (arrows) adjacent to the posterior wall of the stomach. **C.** Another follow-up study 1 year later shows further regression of the lymphoma with radiating folds and a tiny, benign-appearing residual ulcer (arrow) at the site of the previous excavation. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 33-23 Response of duodenal lymphoma to chemotherapy. **A.** CT scan shows a conglomerate mass of adenopathy surrounding the mesenteric vessels. The duodenum is encased by this mass. **B.** Repeat CT scan after two cycles of chemotherapy shows multiple tiny collections of gas in the duodenal wall as a result of rapid tumor lysis and mural necrosis. A tiny amount of free air (arrow) is seen in the peritoneal cavity. This patient had developed clinical signs of peritonitis.

Figure 33-24 Gastric lymphoma on CT. CT scan shows marked thickening of the gastric wall with homogeneous enhancement caused by the infiltrative form of gastric lymphoma. Small perigastric lymph nodes are present in the adjacent fat.

Imaging Modalities

Computed Tomography. CT is the primary imaging modality for the pretreatment evaluation of abdominal lymphoma. It is important to recognize gastric involvement at the time of the initial study. As on barium studies, advanced gastric lymphoma is characterized on CT by infiltrating, polypoid, or ulcerated lesions.^{96,97} In contrast, low-grade gastric MALT lymphomas infrequently produce any abnormalities on CT and, when abnormalities such as wall thickening or masses are detected, endoscopic biopsy specimens almost always reveal high-grade lymphoma.⁹⁸ With more advanced lesions, the most common CT finding is marked thickening of the gastric wall caused by infiltration by tumor (Fig. 33-24). The wall thickening is usually greater and displays a more uniform enhancement pattern than in patients with gastric cancer, unless cavitation is present (see

Figure 33-25 Ulcerated gastric lymphoma on CT. A large ulcer crater (u) is present within a soft tissue mass in the stomach. A, gastric antrum.

Fig. 33-24). Although the gastric contour is usually preserved, the mural stratification seen in the normal stomach and accentuated in hypertrophic gastritis is lost.^{96,97} Other patients may have polypoid or ulcerated masses on CT (Fig. 33-25). Growth into and away from the gastric lumen (endogastric and exogastric growth patterns) are common, and some lesions can directly invade adjacent organs (Fig. 33-26). Any portion of the stomach may be involved by tumor, and transpyloric spread of lymphoma into the duodenum is often detected on CT (Fig. 33-27). The development of lymphadenopathy beyond the expected drainage pathways of primary gastric carcinoma should also favor a diagnosis of gastric lymphoma, but a histologic diagnosis is required before initiating therapy.

Endoscopic Ultrasonography. Endoscopic ultrasonography (EUS) has been shown to be a valuable technique for staging patients with non-Hodgkin's gastric lymphoma, with an overall accuracy of approximately 90%.^{99,100} The findings on EUS may

be highly suggestive of lymphoma, but histologic specimens are required for a definitive diagnosis. Non-Hodgkin's gastric lymphoma may be manifested on EUS by a spectrum of findings, ranging from a hypoechoic mass that disrupts the normal wall layer pattern to selective thickening of the second and third echogenic layers or diffuse thickening of all five wall layers.¹⁰⁰ In patients who are treated nonoperatively, EUS is also useful for documenting the response to therapy.

DIFFERENTIAL DIAGNOSIS

Gastric MALT lymphomas that appear as small polypoid or ulcerated lesions in the stomach may be indistinguishable on barium studies from early gastric cancer. When MALT lymphomas are manifested by multiple, confluent, rounded nodules in the stomach, the differential diagnosis includes severe gastritis, lymphoid hyperplasia, or even a polyposis syndrome involving the stomach. In some cases, this mucosal nodularity may be difficult to differentiate from enlarged areae gastricae, a finding

often associated with *H. pylori* gastritis.¹⁰¹ However, areae gastricae tend to be more uniform in size, producing a sharply margined reticular network. Lymphoid hyperplasia associated with chronic *H. pylori* gastritis may also be manifested by innumerable nodules in the stomach (see Chapter 30).¹⁰² However, the nodules of lymphoid hyperplasia appear as innumerable, tiny, rounded lesions carpeting the antrum or antrum and body of the stomach. Unlike the poorly defined, confluent nodules in low-grade MALT lymphoma, the nodules of lymphoid hyperplasia also tend to have more discrete borders, a more uniform size, and, not infrequently, central umbilications.¹⁰²

Advanced infiltrative gastric lymphomas may be difficult to distinguish radiographically from other causes of thickened gastric folds, such as *H. pylori* gastritis, hypertrophic gastritis, Ménétrier's disease, and gastric carcinoma. Other infiltrative lymphomas may produce a linitis plastica appearance indistinguishable from that of a primary scirrhous carcinoma.¹⁶ Deep endoscopic biopsy specimens are therefore required for a definitive diagnosis.

Ulcerated gastric lymphomas may be impossible to distinguish radiographically from ulcerated carcinomas. Much less frequently, ulcerated lymphomas that have a relatively innocuous appearance can be mistaken for benign gastric ulcers.⁸⁴ When lymphoma is characterized by multiple areas of ulceration, the differential diagnosis includes various inflammatory or infectious conditions involving the stomach, such as Zollinger-Ellison syndrome, Crohn's disease, tuberculosis, syphilis, and cytomegalovirus (see Chapters 29 and 30). However, the correct diagnosis is often suggested by the clinical history.

Polypoid gastric lymphomas may be indistinguishable from polypoid gastric carcinomas. Other lymphomas that appear as submucosal masses can be mistaken for malignant GISTs. Although uncommon, giant cavitated lymphomas may be impossible to differentiate from cavitated GISTs or cavitated metastases. However, malignant GISTs tend to occur as solitary lesions in the stomach, whereas lymphoma and metastatic disease are often manifested by multiple lesions in the stomach, duodenum, and small bowel. In patients with gastric lymphoma, exophytic masses typically demonstrate homogeneous attenuation on CT,^{96,97} whereas malignant GISTs often

Figure 33-26 Gastric lymphoma invading the spleen on CT. The gastric wall is eccentrically thickened (asterisk) by tumor directly invading the splenic parenchyma (arrow).

Figure 33-27 Transpyloric spread of lymphoma into the duodenum. **A.** Barium study shows nodularity and deformity of the distal antrum and pyloric region caused by gastric lymphoma. The duodenal bulb appears normal. **B.** CT scan reveals a lymphomatous mass extending from the distal antrum into the proximal duodenum. have a heterogeneous appearance because of areas of liquefactive necrosis (see later, “Malignant Gastrointestinal Stromal Tumor”).

Bull’s-eye lesions in the stomach may be caused not only by lymphoma but also by Kaposi’s sarcoma, carcinoid tumors, or metastases (particularly those from malignant melanoma). However, lymphomatous lesions tend to be of relatively uniform size, whereas metastases are often of variable size as a result of periodic showers of tumor emboli into the bowel.^{8,12} Benign GISTs that are ulcerated may also have a bull’s-eye appearance, but they usually occur as solitary lesions in the stomach or duodenum.

DUODENAL LYMPHOMA

Duodenal involvement by lymphoma usually results from contiguous spread of tumor from the distal stomach or proximal jejunum (see Fig. 33-27) or from encasement of the duodenum by a conglomerate mass of lymphomatous nodes in the retroperitoneum (see Fig. 33-23A).¹⁰⁵ Because of the paucity of lymphoid tissue in the duodenum, primary duodenal lymphomas are rare lesions, constituting less than 5% of all small bowel lymphomas.¹⁰⁴ As in the stomach, duodenal lymphoma is characterized radiographically by infiltrative, ulcerative, polypoid, and nodular forms.

Duodenal lymphoma may be manifested by a variety of appearances on CT. These include marked and uniform soft tissue attenuation thickening of the duodenal wall (Fig. 33-28), an ulcerated mass (Fig. 33-29), or thickened, exaggerated duodenal folds (Fig. 33-30).

Occasionally, duodenal or small bowel lymphoma may occur as a complication of long-standing celiac disease.^{105,106} Treatment with a gluten-free diet has not been effective in preventing this complication. Thus, periodic radiologic surveillance of the duodenum and small bowel has been advocated to detect developing lymphomas at the earliest possible stage.¹⁰⁶

Malignant Gastrointestinal Stromal Tumor

GISTs are uncommon tumors that constitute only 1% to 3% of all malignant neoplasms in the stomach.^{63,107} These tumors are

often confined to the wall of the stomach for prolonged periods before invading adjacent structures, so they have a better prognosis than gastric adenocarcinomas. Because of their rarity, malignant GISTs in the duodenum are considered separately in a later section.

PATHOLOGY

GISTs are the most common mesenchymal tumors in the GI tract. Most of these tumors are incompletely differentiated or undifferentiated and do not fulfill modern pathologic criteria for classification as leiomyomas or leiomyosarcomas. As a result, the generic designation of gastrointestinal stromal tumors has been widely adopted.¹⁰⁸ GISTs are characterized by positive immunoreactivity for KIT (CD117), a tyrosine kinase growth factor receptor, allowing differentiation from true leiomyomas or leiomyosarcomas.¹⁰⁹ Pharmacologic targeting of these receptors with KIT-tyrosine kinase inhibitors has been shown to be useful for treating patients with GISTs.¹¹⁰

GISTs have been classified pathologically into three categories—spindle cell type (70%), epithelioid type (20%),

Figure 33-28 Duodenal lymphoma on CT. CT scan in an HIV-positive patient shows a large soft tissue mass encasing the third and fourth portions of the duodenum.

Figure 33-29 Ulcerated duodenal lymphoma on CT. **A.** CT scan from a 6-year-old boy shows a soft tissue mass in the duodenum with an air-filled central ulcer crater (arrow). Endoscopic biopsy specimens revealed non-Hodgkin’s lymphoma. **B.** Barium study shows a mass lesion with thickened, irregular folds and a large area of ulceration (arrow) in the third portion of the duodenum.

Figure 33-30 Duodenal lymphoma with exaggerated duodenal folds on CT. Sequential CT images in a patient with jaundice show deformity of the descending duodenum with a homogeneously thickened wall and thickened, exaggerated folds (arrows) caused by biopsy-proven non-Hodgkin's lymphoma. The duodenal lumen contains air and fluid (asterisks). Also note dilation of the common bile duct (arrowhead).

and mixed type (10%).¹¹⁰ The spindle cell type consists histologically of interlacing whorls of spindle-shaped cells with eosinophilic cytoplasm and elongated nuclei.¹¹¹ The less common epithelioid type contains distinctive epithelioid cells with eccentric nuclei and perinuclear vacuolization. In the past, GISTs with an epithelioid morphology were termed *epithelioid leiomyosarcomas* or *leiomyoblastomas*.¹¹²

The stomach is the most common site of GI involvement by malignant GISTs. About 90% involve the fundus and body, and the remaining 10% involve the antrum.¹⁰⁷ These tumors are mesenchymal lesions that usually originate from the outer layer of the muscularis propria. Malignant stromal tumors involving the stomach tend to be large lesions with an average diameter of 10 cm at the time of diagnosis.¹⁰⁷ They often contain large cystic cavities or ulcers because of hemorrhage or necrosis within the tumor.¹¹¹

Malignant GISTs of the stomach may have endogastric or exogastric patterns of growth. Because of their origin in the outer muscular layer, exogastric growth into the abdominal cavity is particularly common.¹¹¹ As they enlarge, exogastric lesions may invade adjacent structures such as the pancreas, colon, or diaphragm. Patients with advanced lesions often have widespread intraperitoneal seeding or hematogenous metastases to the liver.¹¹³ Unlike gastric carcinomas, however, malignant GISTs rarely metastasize to regional lymph nodes, so lymphadenopathy is quite uncommon.¹¹³

The most commonly accepted index of malignancy is the degree of mitotic activity in the tumor. Gastric GISTs smaller than 5 cm and with five or fewer mitoses/50 consecutive

high-power fields (HPF) are most likely benign; GISTs larger than 10 cm and with more than five mitoses/50 HPF are considered malignant; and GISTs that fall between these categories are considered indeterminate lesions with uncertain malignant potential.¹¹⁴ Finally, GISTs with more than 50 mitoses/50 HPF are considered high-grade malignancies that behave in an extremely aggressive fashion.¹¹⁴ However, the degree of mitotic activity, cellular atypia, and nuclear pleomorphism may vary markedly within an individual lesion, so histopathologic criteria are not always reliable for differentiating benign and malignant GISTs.

CLINICAL FINDINGS

Malignant GISTs of the stomach are more common in men,¹¹⁵ usually over 50 years of age.¹¹⁶ The average duration of symptoms at the time of diagnosis is 4 to 6 months.¹⁰⁷ Because malignant GISTs frequently ulcerate, affected individuals often present with signs of upper GI bleeding, including hematemesis, melena, guaiac-positive stool, and iron deficiency anemia.^{109,111} Other common presenting findings include early satiety, bloating, vomiting, abdominal pain, weight loss, and a palpable abdominal mass.^{110,111} However, some patients with exogastric tumors may remain asymptomatic until the lesions have reached enormous sizes.

It is important to be aware of the limitations of endoscopy in diagnosing malignant GISTs because positive endoscopic biopsy specimens may not be obtained unless the overlying mucosa is ulcerated. CT may be performed to determine the

relationship of suspicious lesions to the gastric wall and guide needle aspiration biopsies of endoscopically inaccessible lesions.

Patients with malignant GISTs of the stomach generally have a better prognosis than patients with gastric carcinomas; reported 5-year survival rates range from 20% to 55%.¹¹⁷ Tumors smaller than 5 cm have the best possibility for cure, although it is questionable whether these lesions are all malignant. In contrast, tumors larger than 8 cm are often found to be advanced, unresectable lesions at the time of diagnosis.¹¹⁸ Surgery is the only curative form of therapy. Depending on the extent of tumor, a wedge resection or a subtotal or total gastrectomy may be required. However, malignant GISTs rarely metastasize to regional lymph nodes, so a lymph node dissection is of little therapeutic benefit to these patients. Chemotherapy also is highly ineffective, with a response rate of less than 10%.¹¹⁰ In contrast, imatinib, a tyrosine kinase inhibitor, has been shown to be an effective therapeutic agent for prolonging survival in patients with unresectable lesions or metastatic disease.¹¹⁰

RADIOGRAPHIC FINDINGS

Abdominal radiographs generally have limited value for diagnosing malignant GISTs involving the stomach. Occasionally, however, these tumors may be recognized by the presence of a soft tissue mass indenting the gastric bubble.¹¹⁹ One or more extraluminal gas collections may also be seen in the left upper quadrant as a result of necrosis and cavitation of the tumor.¹²⁰ Rarely, abdominal radiographs may reveal mottled areas of calcification (see Fig. 33-33), but CT is a more sensitive technique for demonstrating this finding (see Fig. 33-35A).¹²¹

More than 90% of patients with malignant GISTs of the stomach have abnormal barium studies,¹⁰⁷ but the correct diagnosis is suggested in only about 50% of cases because of difficulty distinguishing these lesions from benign GISTs or other benign or malignant lesions in the stomach. Intramural lesions typically appear as large, lobulated submucosal masses in the gastric fundus or body (Fig. 33-31).¹⁰⁷ Malignant GISTs may contain one or more ulcers or, not infrequently, large areas of

cavitation (Fig. 33-32).¹⁰⁷ Exogastric lesions may be manifested by giant soft tissue masses that cause extrinsic compression of the adjacent gastric wall (Figs. 33-33 and 33-34).^{107,122} An important clue to the diagnosis of an exogastric tumor is the presence of a central dimple or spicule at the site of attachment or pedicle of the mass (see Fig. 33-34A).¹²³ Rarely, endogastric tumors may appear as polypoid intraluminal masses indistinguishable from primary gastric carcinomas.¹¹¹

The diagnosis of a GIST should be suggested on CT or magnetic resonance imaging (MRI) by the presence of an enhancing mass in the wall of the stomach (Fig. 33-35).^{124,125} Size has been shown to an important predictive feature of malignancy because lesions smaller than 5 cm are more likely to be low-grade tumors (see Fig. 33-35), whereas lesions larger than 5 cm are more likely to be high-grade or frankly malignant tumors (Fig. 33-36).¹²⁶ Large GISTs often have a more exogastric growth pattern and tend to be more heterogeneous and have a greater

Figure 33-31 Malignant gastrointestinal stromal tumor. A large, lobulated submucosal mass is seen in the gastric fundus.

Figure 33-32 Malignant gastrointestinal stromal tumor with cavitation. **A.** A giant mass is present in the stomach. Barium is trapped within irregular cavities in the mass. **B.** Another cavitated lesion is manifested by a giant extraluminal collection of barium (arrows). (A courtesy Hans Herlinger, MD, Philadelphia.)

degree of necrosis than higher grade tumors (Fig. 33-37).¹¹¹ Ulceration or cavitation within malignant GISTs is easily recognized on CT (see Fig. 33-37). CT is particularly helpful for demonstrating the extent of the mass and invasion of adjacent structures (Fig. 33-38).¹²⁷⁻¹²⁹ Rarely, malignant GISTs may be so necrotic that they appear as water-density lesions (Fig. 33-39).

Figure 33-33 Exogastric malignant gastrointestinal stromal tumor with calcification. A giant exogastric mass causes displacement and compression (arrows) of the lesser curvature of the stomach. Mottled areas of calcification are seen in the tumor.

Malignant GISTs in the stomach usually metastasize to the liver and peritoneal cavity (Fig. 33-40); 15% to 47% of patients present with overt metastatic disease to the liver and peritoneum.¹¹⁰ Metastases are usually large heterogeneous lesions. Like the primary tumor, metastases may be multilocular lesions containing fluid-fluid levels and are usually positive on ¹⁸F-FDG-PET/CT. After treatment, liquefied lesions should be carefully inspected to exclude mural nodules, a sign of incomplete response to therapy (see Fig. 33-40). Necrosis and cavitation are particularly common after treatment with tyrosine kinase inhibitors such as imatinib (see Fig. 33-40). Peritoneal involvement by tumor is indistinguishable on CT from other intraperitoneal-seeded metastases.¹³⁰

Malignant GISTs of the stomach are characterized on angiography by relatively well-circumscribed, hypervascular masses with huge feeding arteries and draining veins and intense tumor staining.¹³¹ It is not possible, however, to differentiate benign and malignant GISTs by angiographic criteria. Angiography also is unable to distinguish malignant GISTs from other hypervascular lesions such as carcinoids, neurogenic tumors, and vascular metastases.

DIFFERENTIAL DIAGNOSIS

Because some malignant GISTs may be as small as 2 cm, it is not always possible to distinguish benign and malignant GISTs by radiographic criteria.¹⁰⁸ In general, however, submucosal masses that are larger and more lobulated or contain areas of necrosis or ulceration are more likely to be malignant. The major considerations in the differential diagnosis include lymphoma and other benign or malignant tumors of mesenchymal origin. Cavitated GISTs may be impossible to distinguish radiographically from lymphoma or metastases from malignant melanoma or other tumors. However, patients with lymphoma or metastatic melanoma often have multiple lesions in the stomach and small bowel, whereas cavitory GISTs almost always occur as solitary lesions.

Malignant GISTs that have an exogastric growth pattern can mimic the appearance of extrinsic mass lesions arising in the liver, pancreas, kidney, or mesentery. In such cases, the typical

Figure 33-34 Exogastric malignant gastrointestinal stromal tumor. A. Lateral radiograph of the stomach shows a giant exogastric mass compressing the posterior wall of the gastric fundus (short arrows). A central dimple or spicule (long arrow) is seen at the site of attachment of the mass. This finding should suggest the possibility of an exogastric GIST. **B.** CT scan reveals a giant heterogeneous mass with multiple low-density areas caused by necrosis of tumor. This heterogeneous appearance is characteristic of malignant GISTs on CT. (Courtesy Hans Herlinger, MD, Philadelphia.)

Figure 33-35 Small, low-grade gastrointestinal stromal tumors on CT and MRI. **A.** A low-grade epithelioid lesion is seen on CT as a small (2 cm), well-defined mass (arrow) on the posterior wall of the gastric fundus. Note discrete areas of punctate calcification, an occasional finding in these tumors. **B.** Another low-grade lesion is seen on a 3D gadolinium radial VIBE (volumetric interpolated breath-hold examination) image at MRI as a small (3 cm), homogeneous intramural mass (arrow) at the level of the gastric incisura.

Fig. 33-36 Gastrointestinal stromal tumor with high mitotic activity on CT. Axial CT scan shows a sharply circumscribed heterogeneous mass (asterisk) in the gastric antrum. This heterogeneity on CT should suggest a more high-grade lesion with areas of necrosis.

CT finding of a bulky, heterogeneous mass involving the gastric wall should suggest the correct diagnosis (see Fig. 33-37). Exophytic adenocarcinomas have also been reported, but these lesions are extremely rare.¹³² Occasionally, water-density GISTs may be difficult to distinguish from cystic pancreatic neoplasms or pancreatic pseudocysts. Angiography may be helpful in determining the origin of the mass in these patients. Duplication cysts may also appear on CT as water-density lesions involving the greater curvature of the stomach. However, duplication cysts tend to be smaller and may occasionally communicate with the gastric lumen.^{133,134}

MALIGNANT DUODENAL GASTROINTESTINAL STROMAL TUMOR

Malignant GISTs constitute only 10% of all malignant tumors in the duodenum.¹³⁵ Unlike malignant GISTs of the stomach, the gender distribution is approximately equal.^{135,136} These patients may present with signs of upper GI bleeding, weight loss, abdominal pain, a palpable mass, or obstructive jaundice.^{135,137} Many patients remain asymptomatic until they have advanced lesions. Aggressive surgical treatment (e.g., duodenectomy or pancreaticoduodenectomy) is often advocated.^{135,137} Because malignant duodenal GISTs often invade adjacent structures or metastasize to the liver, these patients have a relatively poor prognosis.¹³⁷

About 80% of malignant duodenal GISTs are located in the second or third portion of the duodenum.¹³⁵ Intramural lesions may appear on barium studies as submucosal masses, often containing areas of ulceration or cavitation (Fig. 33-41).^{135,137} Despite their large size, they rarely cause duodenal obstruction. Other tumors that have an exoenteric growth pattern may be indistinguishable on barium studies from pancreatic neoplasms, pancreatic pseudocysts, or other extrinsic mass lesions involving the duodenum. Like GISTs elsewhere in the GI tract, smaller (<5 cm), more homogeneous duodenal GISTs on CT tend to be low-grade tumors (Fig. 33-42A), whereas GISTs larger than 5cm are more high grade or frankly malignant (Fig. 33-42B). Malignant GISTs usually appear on CT as bulky exophytic masses that enhance heterogeneously because of variable necrosis, ulceration, and cavitation (see Fig. 33-42B).¹³⁸

Kaposi's Sarcoma

The classic form of Kaposi's sarcoma occurs primarily in older men and is manifested by slow-growing violaceous or hemorrhagic lesions on the lower extremities. With the AIDS epidemic that began in the 1980s, patients with this disease were found to develop a much more aggressive form of Kaposi's sarcoma characterized by widespread visceral lesions, particularly in the

Figure 33-37 Malignant gastrointestinal stromal tumors on CT. **A.** A large heterogeneous exogastric mass (asterisk) is seen arising from the posterior wall of the stomach. An ulcer crater (arrow) on the posterior wall of the stomach identifies the gastric wall as the origin of this mass. The heterogeneous enhancement and large size of the lesion strongly correlate with malignant histology. **B.** In another patient, a heterogeneous exogastric mass is seen insinuating between the stomach and pancreas. **C.** In a third patient, a gas- and fluid-filled mass projects posteriorly from the stomach. Although uncommon, this degree of necrosis can occur with malignant GISTs.

GI tract. In various studies, about 35% of patients with AIDS had Kaposi's sarcoma,¹³⁹⁻¹⁴² and about 50% with Kaposi's sarcoma had GI tract involvement.^{140,143-145} The stomach, duodenum, and small bowel were the most common sites of involvement.^{143,146} The colon was affected less frequently, and the esophagus was rarely involved by Kaposi's sarcoma.^{143,146} Demonstration of these lesions has important prognostic implications, so optimal radiographic technique is required when barium studies are performed on patients with AIDS. During the past two decades, however, the development of effective antiviral therapy for human immunodeficiency virus (HIV)-positive patients has markedly decreased the prevalence of AIDS and AIDS-associated conditions such as Kaposi's sarcoma, so this malignancy is not often encountered in modern medical practice.

CLINICAL FINDINGS

For reasons that are unclear, most AIDS patients with Kaposi's sarcoma are homosexuals rather than IV drug abusers or transfusion recipients.^{142,147,148} GI tract involvement by Kaposi's sarcoma is almost always associated with cutaneous disease, but occasional cases have been reported in the absence of skin lesions.^{145,148} Although some patients may present with abdominal pain or upper GI bleeding, Kaposi's sarcoma involving the stomach or duodenum rarely causes symptoms, even if multiple

lesions are present.¹⁴⁸ Instead, GI symptoms usually result from recurrent opportunistic infections in these patients. In fact, patients with Kaposi's sarcoma have a worse prognosis than other patients with AIDS because they are even more likely to develop opportunistic infections.^{141,142,148} In general, GI involvement by Kaposi's sarcoma requires treatment only if it causes symptoms because these lesions rarely affect the progression of AIDS or contribute directly to the patient's death.¹⁴⁸ Radiation or chemotherapy are occasionally used to treat GI Kaposi's sarcoma, but these forms of therapy pose substantial risks in patients who are already immunocompromised.¹⁴⁸

PATHOLOGIC AND ENDOSCOPIC FINDINGS

Kaposi's sarcoma is probably a lesion of vascular origin, consisting histologically of whorled bundles of spindle-shaped cells in a matrix of vascular clefts containing red blood cells and hemosiderin.^{146,149} Gastroduodenal involvement by Kaposi's sarcoma may be manifested on endoscopy by a variety of findings, including flat hemorrhagic patches or macular discolorations, raised, reddish purple nodules, often containing central areas of ulceration (volcano lesions), and coalescent plaques or masses.^{143,144,146,148} Although the gross appearance at endoscopy is characteristic, false-negative biopsy specimens are often obtained because of the submucosal origin of the lesions.^{140,141,143,144,148}

RADIOGRAPHIC FINDINGS

Small macular discolorations of the mucosa cannot be shown on barium studies, so endoscopy is a much more sensitive technique for detecting the earliest GI lesions of Kaposi's sarcoma.^{143,144,146} However, elevated lesions can be shown on barium studies, particularly if double-contrast technique is used.¹⁴⁰ Gastroduodenal involvement may be manifested on barium studies by one or more submucosal defects ranging from 0.5 to 3.0 cm (Fig. 33-43).^{140,146,150,151} As these nodules

Figure 33-38 Malignant gastrointestinal stromal tumor on CT. Off-axis, coronal, volume-rendered MDCT scan shows a large mass arising from the lesser curvature of the stomach. The wall of the lesion (arrowheads) is irregularly thickened.

enlarge, they often ulcerate, producing one or more bull's-eye or target lesions (Fig. 33-44).^{143,146,151} Other patients may have thickened, nodular folds or polypoid masses in the stomach or duodenum (Fig. 33-45).^{140,146} Rarely, an infiltrating form of Kaposi's sarcoma involving the stomach may produce a linitis plastica appearance indistinguishable from that of a primary scirrhous carcinoma (Fig. 33-46).¹⁵² When suspicious lesions are detected in the stomach or duodenum, a small bowel follow-through may be performed to determine whether additional lesions are present in the small bowel.

CT may occasionally demonstrate tumor nodules in the stomach or duodenum caused by Kaposi's sarcoma in AIDS patients who are being evaluated for opportunistic infection (see Fig. 33-44C).^{153,154} CT can also be used to determine whether retroperitoneal adenopathy, splenomegaly, or other evidence of Kaposi's sarcoma is present in the abdomen.^{155,156}

DIFFERENTIAL DIAGNOSIS

Kaposi's sarcoma and non-Hodgkin's lymphoma are the major considerations in the differential diagnosis of multiple, small nodular elevations or bull's-eye lesions in the stomach or duodenum in patients with AIDS.^{140,146} In such cases, the presence of skin lesions should strongly favor Kaposi's sarcoma, whereas the absence of skin lesions should favor lymphoma. Metastases, leukemic infiltrates, or a polyposis syndrome may produce similar findings, but the correct diagnosis is usually suggested on the basis of the clinical history. When ulceration, narrowing, or thickened folds are demonstrated in the stomach, the possibility of opportunistic infections such as cryptosporidiosis, cytomegalovirus, and tuberculosis should also be considered.¹⁵¹ Endoscopic biopsy specimens, brushings, and cultures are therefore required to differentiate Kaposi's sarcoma or other infiltrative lesions from the various opportunistic infections that occur in these patients.

Carcinoid Tumors

Carcinoids are neuroendocrine tumors that are capable of producing a variety of vasoactive substances. Only 2% to 3% of all GI carcinoids are located in the stomach or duodenum.^{157,158} Nevertheless, these lesions are important because they are slow-growing tumors with a well-recognized malignant potential.

Figure 33-39 Malignant gastrointestinal stromal tumor with necrosis on CT. A. Non-contrast-enhanced CT scan shows a water-attenuation mass (asterisk) arising from the anterolateral wall of the stomach. **B.** ¹⁸F-FDG-PET/CT image shows increased activity (arrowheads) in the periphery of the mass. Viable tissue is typically located in the periphery of malignant GISTs that are highly necrotic.

Figure 33-40 High-grade malignant gastrointestinal stromal tumor with intra-abdominal metastases on CT. Coronal CT scan shows metastatic tumor (asterisk) in the liver. Also note malignant ascites and multiple intraperitoneal masses, including a perihepatic diaphragmatic implant (uppermost arrowhead), a subhepatic necrotic peritoneal implant with tumor nodules along its periphery (central arrowheads), and a thick-walled, necrotic pelvic floor implant (lowermost arrowhead). The fluid attenuation of these lesions reflects their response to imatinib, whereas a more homogeneous soft tissue lesion (arrow) in the left abdomen is likely to be a more recent implant.

Figure 33-41 Malignant gastrointestinal stromal tumor of the duodenum. Barium study shows a large intramural mass (arrows) on the lateral border of the descending duodenum.

Figure 33-42 Gastrointestinal stromal tumors of the duodenum on CT. **A.** Coronal MDCT scan shows a small, round, uniformly hyperdense mass (asterisk) in the periampullary region of the duodenum. After the lesion was resected, pathologic specimens revealed a low-grade GIST. **B.** In a different patient, MDCT scan shows a high-grade malignant GIST as a large (>5 cm), heterogeneously enhancing lesion (asterisk) projecting from the lateral wall of the descending duodenum.

Figure 33-43 Kaposi's sarcoma with submucosal masses in AIDS patients. **A.** A solitary submucosal mass (arrow) is seen in the gastric antrum. **B.** In another patient, multiple submucosal masses are present in the stomach. The tiny collections of barium (arrows) seen overlying several anterior wall lesions represent hanging droplets of barium (stalactites) rather than ulcers.

Figure 33-44 Kaposi's sarcoma with bull's-eye lesions in AIDS patients.

A. Multiple bull's-eye lesions or centrally ulcerated submucosal masses (arrows) are present in the gastric antrum. **B.** In another patient, several bull's-eye lesions (arrows) are seen in the descending duodenum. **C.** In a third patient, CT scan shows an ulcerated submucosal mass on the anterior wall of the stomach. Gas outlines the ulcer (arrow). (**B** courtesy Robert Goren, MD, Philadelphia.)

Figure 33-45 Kaposi's sarcoma in an AIDS patient. Multiple polypoid masses are seen on the posterior wall of the fundus.

Figure 33-46 Kaposi's sarcoma with a linitis plastica appearance in an AIDS patient. The stomach has a markedly narrowed, irregular appearance caused by the infiltrating form of Kaposi's sarcoma.

PATHOLOGY

Carcinoid tumors of the stomach usually originate from enterochromaffin-like cells (Kulchitsky cells) arising in the gastric mucosa.^{159,160} These tumors are argyrophilic but argentaffin-negative and lack the enzyme required for the synthesis of 5-hydroxytryptamine (serotonin), so they rarely show

evidence of endocrine function.¹⁶¹ As a result, patients with gastric carcinoids almost never exhibit symptoms of the carcinoid syndrome.

There are three major types of carcinoid tumors. Type I tumors are most common, accounting for 70% to 80% of gastric carcinoids.¹⁵⁸ This type is associated with chronic atrophic gastritis and is usually characterized by one or more small (<1 cm) submucosal masses in the gastric fundus or body with infrequent metastases.¹⁵⁸ In contrast, type II tumors are least common, accounting for only 5% to 10% of gastric carcinoids.¹⁵⁸ Patients with Zollinger-Ellison syndrome (especially those with hypergastrinemia and multiple endocrine neoplasia type 1 [MEN-1 syndrome]) are at high risk for developing type II carcinoid tumors.^{158, 159,160,162-164} It has been shown that hypergastrinemia in these patients causes proliferation of enterochromaffin-like cells responsible for the development of gastric carcinoids. Such carcinoids usually appear as multiple small polyps in the gastric fundus with little, if any malignant potential, so affected individuals have an excellent prognosis.^{159,162} Finally, type III tumors account for 15% to 25% of gastric carcinoids.¹⁵⁸ These lesions usually occur as solitary masses larger than 2 cm and are sporadic tumors that are not associated with atrophic gastritis, Zollinger-Ellison syndrome, or hypergastrinemia.^{159,162} Type III carcinoids are more aggressive lesions, with metastases in 75% of cases.¹⁵⁸

Duodenal carcinoids rarely arise from enterochromaffin cells or produce detectable serotonin levels, so these lesions almost never result in the development of the carcinoid syndrome.¹⁶⁵ Duodenal carcinoids may be associated with Zollinger-Ellison syndrome or neurofibromatosis type 1.¹⁶⁵

CLINICAL FINDINGS

Gastric carcinoids have an equal gender distribution and usually occur in patients over 40 years of age.¹⁶¹ Many patients are asymptomatic, but some may present with abdominal pain, nausea, vomiting, weight loss, anorexia, or signs of upper GI bleeding.^{161,165-168} Although larger lesions are more likely to bleed, massive bleeding of ulcerated carcinoids as small as 1 cm has been described.¹⁶⁹ Gastric carcinoids may be associated with primary hypergastrinemia in patients with Zollinger-Ellison syndrome or with secondary hypergastrinemia in patients with chronic atrophic gastritis.^{159,162,163}

Most gastric carcinoids are low-grade malignant tumors that can eventually metastasize to the liver or other structures. Metastases are found in 20% to 30% of all patients with gastric carcinoids at the time of diagnosis,¹⁵⁸ but long-term survival has been reported, even when regional or hepatic metastases are present. Five-year survival rates approaching 95% have been reported for localized gastric carcinoids versus 5-year survival rates of about 50% for gastric carcinoids of all stages.¹⁶⁰ These patients therefore have a better overall prognosis than those with gastric carcinoma.

RADIOGRAPHIC FINDINGS

Gastric carcinoid tumors associated with hypergastrinemia usually appear on barium studies as multiple small polyps in the gastric fundus or body.¹⁶³ In contrast, sporadic carcinoids may be manifested on barium studies or CT by one or more polypoid or submucosal masses in the stomach (Figs. 33-47 and 33-48).¹⁶¹ Some of the masses may ulcerate,

Figure 33-47 Gastric carcinoid tumors. **A.** A solitary submucosal mass (arrow) is seen in the gastric fundus. **B.** In another patient, multiple submucosal nodules are present in the fundus.

Figure 33-48 Gastric carcinoid tumors on CT. Sequential CT scans show multiple carcinoid tumors as enhancing polypoid masses (arrowheads) in the proximal stomach.

Figure 33-49 Gastric carcinoid tumor. A polypoid mass (arrows) is present on the greater curvature of the gastric antrum. This lesion is indistinguishable from other polypoid tumors in the stomach.

Figure 33-50 Duodenal carcinoid. Barium study shows a smooth, round submucosal mass (arrow) in the duodenal bulb. At surgery, this patient was found to have a malignant duodenal carcinoid tumor involving periduodenal lymph nodes.

producing typical bull's-eye lesions.¹⁶¹ The differential diagnosis for solitary, submucosal-appearing gastric carcinoids includes benign GISTs, ectopic pancreatic rests, and other mesenchymal tumors, whereas the differential diagnosis for multiple gastric carcinoids includes metastases, lymphoma, Kaposi's sarcoma, and gastric involvement by one of the polyposis syndromes. Other patients may have sessile or pedunculated lesions indistinguishable from hyperplastic or adenomatous polyps.^{170,171} Still other patients may have benign-appearing or malignant-appearing gastric ulcers.¹⁶³ Occasionally, advanced carcinoid tumors may appear as large polypoid masses indistinguishable from polypoid carcinomas (Fig. 33-49).^{161,172}

Duodenal carcinoids may be manifested by one or more polypoid defects in the duodenal bulb or proximal descending duodenum.^{165,173-175} These tumors may appear as discrete submucosal masses or intraluminal polyps (Fig. 33-50) or, less frequently, as polypoid or ulcerated lesions on barium studies or CT (Fig. 33-51).^{165,173-175} When gastric or duodenal carcinoids are detected radiographically, endoscopic biopsy specimens are required for a definitive diagnosis.

Miscellaneous Tumors

Other rare malignant tumors that may occur in the stomach or duodenum include liposarcomas, fibrosarcomas, neurofibrosarcomas, plasmacytomas, hemangioendotheliomas, hemangiopericytomas, choriocarcinomas, and malignant autonomic nerve tumors.¹⁷⁶⁻¹⁸¹ Rarely, the stomach may be involved by

Figure 33-51 Duodenal carcinoids on CT. Arterial phase 3D volume-rendered MDCT scan shows two hyperdense masses (arrows) in the duodenal bulb. The larger mass contains a central area of ulceration. Endoscopic biopsy specimens revealed duodenal carcinoid tumors.

leukemia or multiple myeloma (Fig. 33-52).^{182,183} Squamous cell carcinomas and adenosquamous carcinomas have also been described as rare malignant tumors in the stomach arising from congenital rests of squamous epithelium or from preexisting areas of squamous metaplasia.^{184,185}

Figure 33-52 Other malignant tumors involving the stomach. **A.** Innumerable tiny nodules are seen in the gastric fundus as a result of chronic lymphocytic leukemia. **B.** In another patient, multiple submucosal masses are seen in the stomach as a result of multiple myeloma.

Miscellaneous Abnormalities of the Stomach and Duodenum

RONALD L. EISENBERG | MARC S. LEVINE

CHAPTER OUTLINE

Varices

Gastric Varices
Duodenal Varices

Portal Hypertensive Gastropathy

Radiographic Findings

Diverticula

Gastric Diverticula
Duodenal Diverticula

Webs and Diaphragms

Antral Webs and Diaphragms
Duodenal Webs and Diaphragms

Adult Hypertrophic Pyloric Stenosis

Gastric Outlet Obstruction

Duodenal Obstruction

Superior Mesenteric Root Syndrome
Other Causes

Gastric Dilation Without Gastric Outlet Obstruction

Acute Gastric Dilation
Chronic Gastric Dilation and Gastroparesis

Abnormal Extrinsic Masses

Stomach
Duodenum

Widening of the Duodenal Sweep

Pancreatic Diseases Affecting the Stomach and Duodenum

Unusual Filling Defects

Bezoars
Foreign Bodies
Hematomas
Intragastric and Intraduodenal Gallstones

Gastric Volvulus

Gastroduodenal and Duodenojejunal Intussusceptions

Fistulas

Gastrocolic and Duodenocolic Fistulas
Cholecystoduodenal Fistulas
Other Fistulas

Gastric and Duodenal Perforation

Benign Gastric Emphysema

Amyloidosis

Cystic Fibrosis

Varices

GASTRIC VARICES

Pathophysiology

Portal Hypertension. The gastric fundus contains a venous plexus that is normally drained by numerous short gastric veins anastomosing distally with the splenic vein and proximally with branches of the coronary vein as well as venous channels surrounding the distal esophagus. Blood in the short gastric veins normally empties via the splenic vein into the portal venous system. In patients with portal hypertension, however, increased pressure in the portal and splenic veins leads to reversal of blood flow through the short gastric veins into the fundal venous plexus, producing fundal varices. As a result, gastric varices develop in 20% of patients with portal hypertension.¹ Because elevated portal pressure also causes reversal of flow through the coronary vein (producing uphill esophageal varices), some patients with portal hypertension have combined gastric and esophageal varices. However, others with portal hypertension have isolated gastric varices, and an

even greater number have isolated esophageal varices (see Chapter 25).

One explanation for the frequent failure to visualize gastric varices in patients with portal hypertension is that the venous channels in the gastric fundus have thicker, better connective tissue support than the thin-walled, loosely supported veins in the distal esophagus. As a result, varices may be more likely to form in the esophagus than in the stomach, despite comparable elevations in pressure. Even when gastric varices are present, they may be obscured on barium studies or endoscopy by overlying gastric rugae.

Splenic Vein Obstruction. In patients with splenic vein obstruction, increased pressure in the splenic vein beyond the obstruction leads to reversal of flow through the short gastric veins to the fundal plexus of veins, producing gastric varices. Because these patients have normal portal pressure, however, venous blood from the dilated fundal plexus can enter the portal venous system via the coronary vein without producing uphill esophageal varices. As a result, splenic vein obstruction is characterized by isolated varices

in the gastric fundus without associated varices in the esophagus.

Splenic vein obstruction may result from intrinsic thrombosis or, more commonly, from extrinsic compression of the splenic vein by a variety of benign or malignant conditions, including pancreatitis, pancreatic pseudocysts, pancreatic carcinoma, metastatic disease, lymphoma, and retroperitoneal fibrosis or bleeding.²⁻⁵ Intrinsic thrombosis of the splenic vein may be idiopathic or may result from polycythemia or other myeloproliferative disorders.³

Clinical Findings

Gastric varices are important because of the risk of gastrointestinal (GI) bleeding, which can range from low-grade, intermittent bleeding to massive hematemesis.^{6,7} Gastric varices are less likely to bleed than esophageal varices because of their subserosal location and the greater thickness of overlying gastric tissue.⁸ When gastric variceal bleeding occurs, however, it tends to be more severe than esophageal variceal bleeding and is associated with a higher mortality rate.¹ When gastric varices are associated with esophageal varices, affected individuals usually have the stigmata of portal hypertension. In contrast, patients with isolated gastric varices caused by splenic vein obstruction may present with abdominal pain and weight loss from underlying pancreatitis or pancreatic carcinoma.³ Splenomegaly is also a frequent finding in splenic vein obstruction, but a normal-sized spleen does not exclude this condition.⁹

Radiographic Findings

Abdominal Radiographs. Large gastric varices may occasionally be recognized on chest or abdominal radiographs as one or more lobulated soft tissue densities in the gas-filled fundus. Depending on the cause of the varices (portal hypertension or splenic vein obstruction), abdominal radiographs may also reveal splenomegaly, ascites, or pancreatic calcification. When gastric varices are suspected on the basis of abdominal radiographs other imaging tests such as barium studies, endoscopy, or computed tomography (CT) should be performed for a more definitive diagnosis.

Barium Studies. Conventional single-contrast barium studies are thought to be unreliable for detecting gastric varices. Double-contrast technique has therefore been advocated to improve visualization of these structures.^{5,10} Gastric varices may appear as thickened, tortuous folds or as round submucosal filling defects in the gastric fundus, resembling the appearance of a bunch of grapes (Fig. 34-1).^{3,5} Less frequently, a conglomerate mass of fundal varices, also known as tumorous gastric varices, may be manifested by a large polypoid mass that can be mistaken on barium studies for a polypoid carcinoma or even a malignant gastrointestinal stromal tumor (GIST) (Figs. 34-2 and 34-3).^{3,10-13} Tumorous varices have characteristic features, however, appearing in profile as smooth submucosal masses with an undulating contour and discrete borders on the posteromedial wall of the gastric fundus (see Figs. 34-2 and 34-3) and en face as thickened, tortuous folds that fade peripherally into the adjacent mucosa.¹³ These radiographic features should allow differentiation from polypoid gastric neoplasms in most cases. Rarely, dilated gastroepiploic veins may be manifested by varices in the antrum or body of the stomach (Fig. 34-4).¹⁴

When gastric varices are detected on barium studies, it is important to determine whether uphill esophageal varices are

Figure 34-1 Gastric varices. Multiple rounded submucosal filling defects are seen in the gastric fundus, resembling the appearance of a bunch of grapes. (From Levine MS, Kieu K, Rubesin SE, et al: Isolated gastric varices: Splenic vein obstruction or portal hypertension? *Gastrointest Radiol* 15:188-192, 1990.)

also present in these patients. The presence of combined esophageal and gastric varices almost always indicates portal hypertension as the underlying cause. In contrast, isolated gastric varices should raise the possibility of splenic vein obstruction with a patent portal vein (see Fig. 34-3).^{3,5} Nevertheless, portal hypertension is much more common than splenic vein obstruction, so most patients with gastric varices, even in the absence of esophageal varices, are found to have portal hypertension as the underlying cause (see Fig. 34-2).¹⁵ If necessary, CT or angiography may be performed to document the presence of varices and elucidate their pathophysiology.

Computed Tomography. Gastric varices are usually recognized on CT as enhancing, well-defined, round or tubular densities on the posterior or posteromedial wall of the gastric fundus (Fig. 34-5).¹⁶ CT is more sensitive than conventional radiologic examinations in detecting these lesions because barium studies can only demonstrate varices that protrude into the lumen, whereas CT can delineate deeper intramural and perigastric varices.¹⁶ CT may also reveal cirrhotic liver disease, splenomegaly, or ascites in patients with portal hypertension (see Fig. 34-5) and splenomegaly or pancreatic disease in patients with splenic vein obstruction.

Angiography. Angiography may be performed to confirm the presence of gastric varices and determine the nature of the underlying venous abnormality. With portal hypertension, reversal of flow through the coronary and short gastric veins leads to the formation of esophageal and gastric varices, with absent visualization of the portal and splenic veins. With splenic vein obstruction, however, delayed images reveal normal filling of a patent portal vein without evidence of esophageal varices, as blood is diverted from the fundal plexus of veins via the coronary vein to the portal venous system, bypassing the

Figure 34-2 Conglomerate mass of gastric varices (also known as tumorous varices). **A.** Barium study shows a large, lobulated submucosal mass (arrows) on the medial aspect of the gastric fundus. Although this lesion could be mistaken for a malignant GI stromal tumor or even a polypoid carcinoma, note its smooth undulating contour. **B.** Unenhanced CT scan shows a lobulated soft tissue mass (arrows) on the posteromedial wall of the fundus. **C.** Endoscopic photograph shows a conglomerate mass of varices (arrows) in the gastric fundus adjacent to the cardia. This patient had underlying portal hypertension. (B and C from Levine MS, Kieu K, Rubesin SE, et al: Isolated gastric varices: Splenic vein obstruction or portal hypertension? *Gastrointest Radiol* 15:188–192, 1990.)

Figure 34-3 Conglomerate mass of isolated gastric varices caused by splenic vein obstruction. A smooth, undulating mass (arrows) is seen on the posteromedial wall of the gastric fundus. Note the resemblance to the gastric varices in Figure 34-2. This patient had underlying pancreatitis causing splenic vein obstruction. (Courtesy William M. Thompson, MD, Minneapolis.)

Figure 34-4 Nonfundal gastric varices. Thickened, tortuous folds are seen in the body of the stomach caused by markedly dilated gastroepiploic veins. This patient had severe portal hypertension. (From Levine MS: *Radiology of the Esophagus*. Philadelphia, WB Saunders, 1989.)

Figure 34-5 Gastric varices on CT. Enhancing collaterals are seen in the gastric wall (arrowheads), gastrohepatic ligament (open arrows), and left retroperitoneal space. This patient also has cirrhosis with splenomegaly and minimal ascites (solid arrow) caused by portal hypertension. S, stomach; SP, spleen. (Courtesy Richard M. Gore, MD, Evanston, IL.)

Figure 34-6 Angiographic demonstration of gastric varices due to splenic vein obstruction. Image from the venous phase of a splenic arteriogram shows a densely opacified spleen with absent visualization of the splenic vein, extensive gastric varices (G), and a dilated coronary vein (cv) diverting blood from the fundal plexus of veins to the portal vein (pv). Note the presence of a dilated gastroepiploic vein (gev). (Courtesy Dana R. Burke, MD, Bethesda, MD.)

obstructed splenic vein (Fig. 34-6). Thus, portal hypertension can usually be differentiated from splenic vein obstruction by angiography, so appropriate therapy can be instituted in these patients.

Differential Diagnosis

When gastric varices are manifested on barium studies by thickened, nodular folds in the fundus, the differential diagnosis

Figure 34-7 Duodenal varices. Thickened, serpiginous folds are seen in the proximal descending duodenum.

includes *Helicobacter pylori* gastritis, Ménétrier's disease, Zollinger-Ellison syndrome, pancreatitis, and lymphoma.¹⁷ However, gastric varices tend to be more tortuous or lobulated than these other conditions and are often associated with esophageal varices. Occasionally, a conglomerate mass of fundal varices may resemble a polypoid carcinoma or even a malignant GIST (see Figs. 34-2 and 34-3).^{3,10-13} However, the vascular origin of these lesions is suggested by their smooth undulating contour and typical location on the posteromedial wall of the gastric fundus. CT or angiography may be required for a definitive diagnosis. It is particularly important to differentiate gastric varices from other lesions before performing endoscopic biopsy or surgery because inadvertent perforation of a varix may lead to catastrophic GI bleeding.

Treatment

Emergent treatment for bleeding gastric varices is rarely necessary. When major bleeding does occur in patients with splenic vein obstruction, the patients are almost always cured by simple splenectomy because portal venous pressure is normal in these individuals.¹⁸ In contrast, some form of portosystemic shunt may be required for gastric varices caused by portal hypertension, as splenectomy alone has no effect on portal venous pressure in these patients. Thus, the choice of treatment for gastric varices depends on the underlying cause.

DUODENAL VARICES

Duodenal varices typically appear on barium studies as thickened, serpiginous folds in the proximal duodenum (Fig. 34-7).

They are almost always associated with esophageal varices and may be complicated by GI bleeding. Occasionally, an isolated duodenal varix can present as a solitary filling defect.¹⁹

Portal Hypertensive Gastropathy

Portal hypertensive gastropathy is a distinct pathologic entity caused by chronic portal hypertension.²⁰ Chronic venous congestion in the stomach results in mucosal hyperemia, capillary ectasia, and increased numbers of submucosal arteriovenous communications with dilated arterioles, capillaries, and veins in the gastric wall.²¹ For reasons that are unclear, portal hypertensive gastropathy occurs more frequently in patients with cirrhosis than in other patients with portal hypertension. This condition is a cause of acute and chronic upper GI bleeding, even in the absence of esophageal or gastric varices. It has been estimated that nonvariceal bleeding from portal hypertensive gastropathy is responsible for up to 30% of all cases of upper GI bleeding in patients with portal hypertension.²²

RADIOGRAPHIC FINDINGS

Portal hypertensive gastropathy predominantly involves the gastric fundus and is manifested on barium studies by thickened, nodular folds with undulating contours and indistinct borders (Fig. 34-8).²³ Although the pathophysiologic basis for this fold thickening is uncertain, it could result from a combination of mucosal hyperemia and dilated submucosal vessels. Gastric varices may also appear as thickened folds on barium studies, but the folds tend to have a more serpentine configuration and are often associated with discrete submucosal masses (see Fig. 34-1). The differential diagnosis also includes various forms of gastritis (especially *H. pylori* gastritis), lymphoma, and, rarely, Ménétrier's disease.

Figure 34-8 Portal hypertensive gastropathy. Thickened, nodular folds are seen in the gastric fundus. Note how the folds have an undulating contour and indistinct borders. Although gastric varices could produce a similar appearance, they tend to have a more serpentine configuration and are often manifested by discrete submucosal masses (see Fig. 34-1). (From Chang D, Levine MS, Ginsberg GG, et al: Portal hypertensive gastropathy: Radiographic findings in eight patients. *AJR* 175:1609–1612, 2000.)

Diverticula

GASTRIC DIVERTICULA

Gastric diverticula almost always arise on a discrete neck from the posterior wall of the fundus and usually cause no symptoms. Barium studies best show a gastric fundal diverticulum in profile on lateral views of the fundus, but a collection of barium pooling within the diverticulum can occasionally mimic an area of ulceration (Fig. 34-9).

Intramural or partial gastric diverticulum is a rare anomaly of no clinical importance that is characterized by focal invagination of the mucosa into the muscular layer of the gastric wall.²⁴ These structures are almost always located on the greater curvature of the distal antrum. The diverticulum may be manifested on barium studies by a tiny collection of barium extending outside the contour of the adjacent gastric wall (Fig. 34-10). Although these structures can be mistaken for ulcers or even ectopic pancreatic rests on the greater curvature, they tend to have a changeable configuration at fluoroscopy, whereas true ulcers have a fixed appearance.

DUODENAL DIVERTICULA

True Diverticula

Duodenal diverticula are detected as incidental findings on upper GI barium studies in up to 15% of patients. The diverticula are acquired lesions, consisting of a sac of mucosal and submucosal layers herniating through a muscular defect. These diverticula often fill and empty by gravity as a result of pressure generated by duodenal peristalsis. Most duodenal diverticula are located on the medial border of the descending duodenum in the periampullary region (Fig. 34-11), but they not infrequently are found in the third or fourth portion of the duodenum and can occasionally be located on the lateral border of the descending duodenum (Fig. 34-12).

Figure 34-9 Gastric diverticulum. A large diverticulum is seen arising from the posterior wall of the fundus. Pooling of barium (arrowheads) in the diverticulum could be mistaken for an area of ulceration. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-10 Intramural or partial gastric diverticulum. A tiny barium-filled outpouching (arrow) is seen on the greater curvature of the distal antrum. There is a heaped-up area overlying the diverticulum that could be mistaken for an ectopic pancreatic rest.

Figure 34-11 Duodenal diverticulum. A typical diverticulum (arrows) is seen arising from the medial border of the descending duodenum. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Duodenal diverticula typically appear on barium studies as smooth, round or ovoid outpouchings arising on a discrete neck from the medial border of the descending duodenum (see Fig. 34-11). They are often multiple and may change in size and shape at fluoroscopy. The lack of inflammatory reaction (spasm or edema) allows a duodenal diverticulum to be differentiated from a postbulbar ulcer. Bizarre multilobulated or giant diverticula are occasionally seen.²⁵ Filling defects representing inspissated food particles or blood clots can sometimes be found within the diverticulum (Fig. 34-13).

When duodenal diverticula contain gas or a combination of fluid and gas, they are readily visible on CT. However, a diverticulum that is predominantly fluid-filled can occasionally mimic the CT findings of a cystic neoplasm in the head of the pancreas (Fig. 34-14A).²⁶ The correct diagnosis can still be established, however, if intradiverticular gas is identified (Fig. 34-14B).²⁶

More than 90% of patients with duodenal diverticula are asymptomatic.²⁷ Occasionally, however, these patients may develop serious complications such as duodenal diverticulitis, upper GI bleeding, gastric outlet obstruction, and pancreatobiliary disease. Because duodenal diverticula are retroperitoneal structures, duodenal diverticulitis and perforation can occur without clinical signs of peritonitis or radiographic signs of free intraperitoneal air. Instead, abdominal radiographs may reveal localized retroperitoneal gas adjacent to the duodenum and upper pole of the right kidney.²⁸ Studies with barium or water-soluble contrast agents may demonstrate localized extravasation of contrast material from the perforated diverticulum into a contained extraluminal collection or a deformed diverticulum secondary to a previous perforation that subsequently sealed off.²⁹ CT is particularly helpful for showing a

Figure 34-12 Lateral duodenal diverticulum. A diverticulum (long arrow) is seen arising from the lateral border of the descending duodenum. Note how the diverticulum has a discrete neck (short arrow). Also note how the diverticulum is compressing the adjacent duodenum.

contained perforation or inflammatory changes involving adjacent structures.³⁰

Rarely, duodenal diverticula may cause massive upper GI bleeding.³¹ In such cases, scanning with ^{99m}Tc-labeled red blood cells or angiography may be required to localize the site of bleeding.³¹ Duodenal diverticula have also been described as a rare cause of duodenal or even biliary obstruction. Anomalous insertion of the common bile duct and pancreatic duct into a duodenal diverticulum can be demonstrated in about 3% of carefully performed T-tube cholangiograms.³² This anatomic

variation can impair drainage of bile into the duodenum, predisposing these patients to biliary obstruction, bile duct stones, and pancreatitis.

Pseudodiverticula

Pseudodiverticula are exaggerated outpouchings or sacculations of the inferior and superior recesses of the duodenal bulb related to acute or chronic duodenal ulcer disease (Fig. 34-15).

Figure 34-13 Duodenal diverticulum with a blood clot. This diverticulum contains a large, irregular filling defect representing a blood clot in a patient with recent upper GI bleeding. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-15 Duodenal pseudodiverticula. Two exaggerated outpouchings or pseudodiverticula (arrows) are seen at the base of the bulb caused by scarring from previous peptic ulcer disease.

Figure 34-14 Duodenal diverticulum mimicking a cystic pancreatic neoplasm on CT. **A.** CT scan with oral and intravenous contrast material at the level of the pancreatic head shows a fluid-filled cystic lesion (long arrow) that was initially thought to represent a cystic pancreatic tumor. Note air and contrast material in the duodenum (short arrow). **B.** A follow-up CT scan at a similar level 6 months later shows filling of the diverticulum with gas (arrow), confirming the diagnosis of a duodenal diverticulum. (From Macari M, Lazarus D, Israel G, et al: *Duodenal diverticula mimicking cystic neoplasms of the pancreas: CT and MR imaging findings in seven patients*. *AJR* 180:195-199, 2003.)

Figure 34-16 Intraluminal duodenal diverticulum. **A.** The finger-like, barium-filled sac in the descending duodenum is separated from barium in the adjacent lumen by a radiolucent band (arrows) representing the wall of the diverticulum. **B** and **C.** Axial (**B**) and coronal (**C**) CT scans also show the barium-filled intraluminal sac separated from barium in the adjacent duodenal lumen by a thin lower density web (arrows).

The sacculations may be caused by edema and spasm associated with an active ulcer or by asymmetric fibrosis and retraction associated with scarring from a healed ulcer. However, the degree of deformity is not directly related to the size of the ulcer because some small duodenal ulcers may produce large sacculations, whereas other large ulcers may have little or no effect on the contour of the bulb.

Intraluminal Diverticula

An intraluminal duodenal diverticulum is a sac of duodenal mucosa originating from the second portion of the duodenum near the papilla of Vater. The term *intraluminal diverticulum* is actually a misnomer because this structure is not a diverticulum, but begins as a congenital duodenal web or diaphragm containing a small central aperture; the web gradually elongates over time because of forward pressure by food and duodenal peristalsis.³³ As a result, the diverticulum usually extends antegrade into the distal descending duodenum or, occasionally, the third or fourth portion of the duodenum. When filled with barium, this structure has a characteristic radiographic appearance on barium studies and abdominal CT, with a finger-like intraluminal sac separated from barium in the adjacent lumen by a thin radiolucent stripe representing the elongated web, or “wall,” of the diverticulum (Fig. 34-16).^{33,34} Because of the resemblance to a wind sock at small airports, this structure has also been called a “wind sock” diverticulum.

Both an intraluminal duodenal diverticulum and congenital duodenal diaphragm can be associated with a variety of other anomalies, including annular pancreas, midgut volvulus, situs inversus, choledochoceles, congenital heart disease, Down syndrome, imperforate anus, Hirschsprung’s disease, omphalocele, and exstrophy of the bladder.

Patients with an intraluminal duodenal diverticulum may present with nausea and vomiting from associated duodenal obstruction.³³ The usual treatment is surgery, but some patients may benefit from endoscopic disruption of the underlying duodenal web responsible for their symptoms, avoiding the need for surgery.³³

Webs and Diaphragms

ANTRAL WEBS AND DIAPHRAGMS

Antral webs and diaphragms are thin membranous septa that are usually located within 3 cm of the pyloric canal and are oriented perpendicular to the long axis of the stomach.³⁵ Clinical symptoms of partial gastric outlet obstruction correlate with the size of the central aperture of the web or diaphragm; obstructive symptoms do not occur if the diameter of the aperture is greater than 1 cm. Even with minute central orifices as small as 2 mm, these diaphragms may not cause obstructive symptoms until adult life.

Nonobstructive antral webs and diaphragms appear on barium studies as persistent, sharply defined, 2- to 3-cm-wide, band like defects in the barium column occurring at right angles to the gastric wall (Fig. 34-17).³⁵ A similar appearance may be produced by a prominent transverse antral fold, but transverse folds do not generally extend across the gastric lumen, and they are not perfectly straight. Antral webs and diaphragms are best visualized when the antrum is adequately distended proximal and distal to this structure. Occasionally, the antrum distal to the web can be mistaken radiographically for the duodenal bulb (Fig. 34-18) or, less frequently, for a gastric diverticulum or ulcer. With severe obstruction, gastric emptying is greatly delayed, and barium can be seen to pass in a thin stream (jet phenomenon) through the central orifice of the web.³⁶

DUODENAL WEBS AND DIAPHRAGMS

Duodenal webs and diaphragms are weblike projections in the duodenal lumen that cause varying degrees of obstruction. Most reported cases have involved the second portion of the duodenum near the ampulla of Vater. A congenital duodenal web usually appears on barium studies as a thin radiolucent line extending across the lumen, often associated with proximal duodenal dilation (Fig. 34-19). Because the obstruction is

Figure 34-17 Antral mucosal diaphragm. A bandlike defect (black arrows) is seen arising at right angles to the gastric wall. The web is approximately 5 mm in thickness. The pyloric channel is denoted by white arrows. (From Bjorgvinsson E, Rudzki C, Lewicki AM: Antral web. *Am J Gastroenterol* 79:663–665, 1984.)

Figure 34-18 Antral mucosal diaphragm. The lumen is so narrowed by the diaphragm (arrow) that the antrum distal to the diaphragm could be mistaken for the duodenal bulb. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

incomplete, small amounts of gas may be present in more distal portions of the bowel.³⁷ Rarely, a web may balloon distally, forming an intraluminal duodenal diverticulum (see earlier, “[Intraluminal Diverticula](#)”). Although the vast majority of duodenal webs and diaphragms are thought to be congenital, acquired duodenal diaphragms similar to those in the small bowel have been described as a rare complication of long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs).³⁸

Figure 34-19 Duodenal web. There is high-grade stenosis of the second portion of the duodenum. The presence of gas in the bowel distal to the web indicates that the obstruction is incomplete. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Adult Hypertrophic Pyloric Stenosis

The histologic, anatomic, and radiographic abnormalities in adult hypertrophic pyloric stenosis are indistinguishable from those in the infantile form.³⁹ The disease in adults may represent a milder form of the same entity observed in infants and children. Most cases of adult hypertrophic pyloric stenosis go unrecognized because these individuals are asymptomatic. However, some patients complain of nausea and vomiting, epigastric pain, weight loss, or anorexia, and approximately 50% of patients with adult hypertrophic pyloric stenosis have associated gastric ulcers. These ulcers probably develop as a result of delayed gastric emptying with increased gastrin production and hyperacidity. In contrast to children, adults with this condition rarely develop high-grade gastric outlet obstruction.

Adult hypertrophic pyloric stenosis is typically manifested on barium studies by elongation and narrowing of the pyloric canal as a result of a hypertrophied pyloric muscle ([Fig. 34-20](#)).³⁹ The pylorus can be as long as 2 to 4 cm in these patients (the normal length is <1 cm in adults). The proximal end of the narrowed pylorus merges gradually with the adjacent antrum, producing a smooth, tapered juncture without the shoulders expected for a malignant neoplasm. In contrast, the distal end of the hypertrophied pyloric muscle may bulge into the duodenum, producing a distinctive concave indentation on the base of the duodenal bulb (see [Fig. 34-20](#)).³⁹ Some patients may have findings of gastric outlet obstruction.

Gastric Outlet Obstruction

Peptic ulcer disease is the most common cause of gastric outlet obstruction in adults, accounting for about two thirds of cases

Figure 34-20 Adult hypertrophic pyloric stenosis. The pyloric canal is narrowed and elongated, with a characteristic concave indentation (arrows) on the base of the duodenal bulb caused by bulging of the pyloric muscle mass into the duodenum.

(Fig. 34-21). The ulcers are usually located in the duodenal bulb, but may also be located in the pyloric channel or gastric antrum or, rarely, in the gastric body. Narrowing of the lumen in peptic ulcer disease can result from acute inflammation, edema and spasm, muscular hypertrophy, or fibrosis and scarring. In many cases, more than one of these factors contributes to the development of gastric outlet obstruction. Most patients with peptic ulcer disease causing pyloric obstruction have a long-standing history of ulcer symptoms. A gastric carcinoma should therefore be suspected when gastric outlet obstruction develops in previously asymptomatic patients.

An annular carcinoma of the distal antrum or pylorus is the second most common cause of gastric outlet obstruction, accounting for nearly one third of cases (Fig. 34-22). Occasionally, metastases to the stomach or other malignant tumors may also produce obstructive symptoms. In contrast to patients with peptic ulcer disease, patients with gastric outlet obstruction caused by malignant tumors often have recent onset of abdominal pain and weight loss.⁴⁰

Abdominal radiographs in patients with gastric outlet obstruction often demonstrate the outline of the dilated, gas-filled stomach. Barium studies may reveal mottled, nonopaque material representing retained food and debris in the stomach. Depending on the degree of obstruction, there can be a marked delay in gastric emptying, with barium sometimes retained in the stomach for 24 hours or longer. Over time, the stomach may become enormously dilated, extending inferiorly into the lower abdomen or even the pelvis. In patients with gastric outlet obstruction, the radiologist must always attempt to differentiate a benign lesion (e.g., peptic ulcer disease) from a malignant lesion (e.g., gastric carcinoma) as the cause of obstruction on barium studies. The presence of a persistent collection of barium within the duodenal bulb, pyloric channel, or prepyloric gastric antrum should suggest peptic ulcer disease as the

Figure 34-21 Gastric outlet obstruction caused by peptic ulcer disease. Note gastric distention and dilution of ingested barium by retained fluid in the stomach. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-22 Gastric outlet obstruction caused by an annular carcinoma of the antrum. There is irregular narrowing of the distal antrum (arrow) with proximal dilation of the stomach. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

likely cause of obstruction. Distortion and scarring of the bulb, with associated pseudodiverticula, should also suggest ulcer disease as the likely cause of obstruction. Conversely, the presence of a discrete mass, nodularity, or irregularity in the adjacent antrum should suggest a malignant tumor. Nevertheless, it is not always possible to differentiate benign and

malignant cases of gastric outlet obstruction on radiographic criteria. When gastric carcinoma cannot be excluded, endoscopy or even surgical exploration may be required for a definitive diagnosis.

Gastric outlet obstruction may occasionally be caused by other conditions involving the stomach and duodenum. Granulomatous diseases such as Crohn's disease, sarcoidosis, syphilis, and tuberculosis may cause marked antral narrowing and obstruction (Fig. 34-23). Severe pancreatitis or cholecystitis

Figure 34-23 Gastric outlet obstruction caused by Crohn's disease. There is tapered narrowing of the distal antrum caused by Crohn's disease involving the stomach. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

may cause intense spasm and edema of the adjacent duodenum with associated gastric outlet obstruction.⁴¹ Antral narrowing and obstruction may also be caused by other rare conditions such as amyloidosis (see later, "Amyloidosis") and scarring from previous ingestion of corrosive substances.

Prolapse of a benign antral polyp into the duodenum may occasionally produce intermittent gastric outlet obstruction, with an intraluminal filling defect seen at the base of the duodenal bulb. Other conditions causing gastric outlet obstruction include antral mucosal webs and diaphragms, adult hypertrophic pyloric stenosis, and gastric volvulus (these conditions are discussed elsewhere in the chapter).

Duodenal Obstruction

A variety of congenital anomalies, inflammatory disorders, and malignant tumors may cause duodenal obstruction. Many of these conditions are discussed elsewhere in the text.

SUPERIOR MESENTERIC ROOT SYNDROME

The transverse portion of the duodenum has a fixed position in the retroperitoneum. As a result, this portion of the duodenum is in a closed compartment bounded anteriorly by the root of the mesentery, which carries the superior mesenteric vessel sheath (artery, vein, and nerve), and posteriorly by the aorta and lumbar spine (at the L2-3 level), where the lumbar lordosis is most pronounced. Even in asymptomatic people, there is often a transient delay of barium where the transverse duodenum crosses the spine. This delay can be associated with mild, inconstant dilation of the proximal duodenum (Fig. 34-24).

Any process that tends to close the nutcracker-like jaws of the aortomesenteric angle results in some degree of compression of the transverse portion of the duodenum. This phenomenon is most likely to occur in asthenic persons, particularly those who rapidly lose weight and retroperitoneal fat because of debilitating illness; the increased dragging effect of the mesenteric root in these patients narrows the aortomesenteric

Figure 34-24 Asymptomatic patient with findings mimicking those of superior mesenteric root syndrome. **A.** Frontal view shows an extrinsic, vertically oriented, bandlike defect (arrow) and apparent obstruction of the third portion of the duodenum by the superior mesenteric root. **B.** Prone, right anterior oblique view obtained moments later shows a normal duodenal sweep without evidence of obstruction.

Figure 34-25 Superior mesenteric root syndrome caused by scleroderma. The duodenum is markedly dilated and atonic proximal to an extrinsic, vertically oriented, bandlike defect (arrow) at the aortomesenteric angle. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

angle. Prolonged bed rest or immobilization in the supine position (e.g., patients with body casts or whole-body burns or patients fixed in a position of hyperextension after spinal injury or surgery) also causes the mesenteric root to compress the anterior aspect of the transverse duodenum, resulting in varying degrees of duodenal obstruction.^{42,43}

In patients with scleroderma or other causes of decreased duodenal peristalsis, the combination of the lumbar spine, aorta, and mesenteric root may constitute enough of a barrier to cause substantial obstruction of the transverse duodenum. As a result, the superior mesenteric root syndrome sometimes occurs in patients with scleroderma, who have a dilated atonic duodenum proximal to the level of the superior mesenteric root (Fig. 34-25). Other collagen diseases such as dermatomyositis and systemic lupus erythematosus may produce similar radiographic findings. In Chagas' disease, inflammatory destruction of intramural autonomic plexuses by *Trypanosoma cruzi* can lead to generalized GI aperistalsis and dilation that usually involve the esophagus and colon but can also affect the duodenum. Disordered duodenal motility and dilation can also result from neuropathies associated with diabetes, porphyria, and thiamine deficiency or from surgical vagotomy for peptic ulcer disease or chemical vagotomy from drugs such as atropine, morphine, and diphenoxylate (Lomotil).

Any space-occupying process within the aortomesenteric angle can also compress the transverse duodenum, causing the superior mesenteric root syndrome. As a result, inflammatory thickening of the bowel wall or mesenteric root by pancreatitis, Crohn's disease, and peptic ulcer disease or neoplastic thickening of the mesenteric root by metastases to the mesentery or mesenteric lymph nodes can lead to duodenal obstruction.⁴⁴ Occasionally, a metastatic tumor involving the duodenum may cause delayed gastric emptying and massive gastric dilation out of proportion to the degree of duodenal obstruction, possibly because of injury to the vagal nerve by retroperitoneal tumor.⁴⁵

Regardless of the underlying pathophysiology, the superior mesenteric root syndrome is associated with characteristic radiographic findings. Barium studies usually reveal marked dilation of the first and second portions of the duodenum associated with an extrinsic, vertically oriented, bandlike defect in the transverse portion of the duodenum overlying the spine (see Fig. 34-25). In some cases, obstruction may be partially relieved by placing the patient in the prone position. CT may demonstrate beaklike compression of the third portion of the duodenum between the superior mesenteric vessels and aorta, thereby confirming the diagnosis of the superior mesenteric root syndrome.⁴⁶

OTHER CAUSES

Intramural hematoma, intraluminal duodenal diverticulum, and aortoduodenal fistula (discussed elsewhere in this chapter) are other causes of duodenal obstruction. Ulceration with stricture formation can also be a complication of radiation therapy to the upper abdomen.⁴⁷ A rare cause of duodenal obstruction is the preduodenal portal vein, which crosses in front of the duodenum, rather than behind it. This anomaly is associated with other malformations such as duodenal bands and annular pancreas, which are more likely to be the cause of obstruction than the anomalous crossing vessel. The major reason to be aware of the preduodenal portal vein is so it is not injured at the time of surgery for these other malformations.⁴⁸

Gastric Dilation Without Gastric Outlet Obstruction

Acute or chronic dilation of the stomach with prolonged retention of food or barium can occur in the absence of gastric outlet obstruction. Gastric retention is defined as vomiting of food eaten more than 6 hours earlier or the presence of food in the stomach at the time of an upper GI series (assuming that the patient has not eaten for 8 to 10 hours). However, gastric retention is not synonymous with gastric outlet obstruction, and corrective surgery is not always indicated for these patients.⁴⁹

The appearance of nonobstructive gastric dilation is indistinguishable from that of organic gastric outlet obstruction. Abdominal radiographs may reveal a massively dilated, gas- and fluid-containing stomach extending inferiorly into the lower abdomen or pelvis (Fig. 34-26). Administration of barium confirms the presence of a dilated stomach with decreased or absent gastric peristalsis and a large amount of retained food and debris in the lumen.

ACUTE GASTRIC DILATION

Acute gastric dilation is characterized by sudden, severe distention of the stomach, usually occurring within several days after abdominal surgery (Fig. 34-27). In affected individuals, a normal stomach can expand rapidly into a hyperemic, cyanotic, atonic sac that fills the abdomen. This postoperative complication has become much less common as a result of improved operative and postoperative care, including meticulous handling of tissues at surgery, better anesthetics, nasogastric suction, and careful monitoring of acid-base and electrolyte balances. Acute gastric dilation may also occur as a complication of other

medical or surgical conditions, including abdominal trauma and peritoneal inflammatory processes.

Appropriate therapy usually produces a rapid clinical response but, if untreated, acute gastric dilation may be a life-threatening condition. Pain is seldom severe until these patients have marked gastric dilation. Aerophagia (air swallowing) in some patients may also contribute to rapid gaseous distention of the stomach. In fulminant cases, acute gastric dilation may cause severe vomiting, aspiration, fluid and electrolyte disturbances, dehydration, perforation, peritonitis, and shock.⁵⁰

CHRONIC GASTRIC DILATION AND GASTROPARESIS

The two most common causes of chronic gastric dilation and gastroparesis are diabetes and narcotics. Some patients are asymptomatic, but others develop chronic nausea, vomiting, bloating, early satiety, and postprandial abdominal fullness.⁵¹⁻⁵³ About 40% of patients with diabetes have a dilated stomach with decreased or absent gastric peristalsis and delayed gastric emptying (diabetic gastropathy).⁵² Most of these patients have long-standing, poorly controlled diabetes associated with a peripheral neuropathy or other complications.⁵¹ Narcotic medications may also cause marked gastroparesis that gradually resolves after withdrawal of the offending agent. Other patients with neurologic abnormalities (e.g., brain tumors, bulbar poliomyelitis, tabes dorsalis) may develop chronic gastric retention, although these patients are more likely to develop esophageal dysmotility. Marked gastric dilation may also develop in patients with scleroderma, polymyositis, dermatomyositis, myotonic muscular dystrophy, electrolyte and acid-base imbalances, lead poisoning, and porphyria (Fig. 34-28).^{54,55}

The radiologic diagnosis of gastroparesis is typically made on the basis of an endoscopic examination showing no evidence of gastric outlet obstruction combined with a nuclear medicine solid emptying scan showing delayed emptying of solids from the stomach.⁵² In patients with nausea and vomiting or other related symptoms, however, the diagnosis of gastroparesis can also be established on barium studies showing decreased or absent gastric peristalsis at fluoroscopy, with varying degrees of gastric dilation and delayed emptying of barium from the stomach in the absence of findings of mechanical gastric outlet obstruction.⁵³ Barium studies are therefore extremely helpful for differentiating gastroparesis from gastric outlet obstruction in patients with nausea and vomiting.

Abnormal Extrinsic Masses

STOMACH

Extrinsic impressions on the stomach may be caused by a prominent left lobe of the liver, aberrant position of the spleen or left kidney, or pathologic enlargement of any of these structures (Fig. 34-29). CT can aid in differentiating these extrinsic defects from true gastric lesions.

DUODENUM

A variety of abnormalities involving organs in the right upper quadrant may cause displacement of or extrinsic impressions on the duodenal bulb and sweep. A dilated common bile duct typically produces an obliquely oriented, tubular indentation

Figure 34-26 Massive gastric dilation. Abdominal radiograph shows an enormous amount of gas filling a markedly dilated stomach that extends inferiorly into the pelvis. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-27 Acute gastric dilation from recent abdominal surgery. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-28 Chronic gastric dilation caused by severe electrolyte and acid-base imbalances. **A.** Abdominal radiograph shows a marked amount of particulate material in a massively dilated stomach extending inferiorly into the pelvis. **B.** Barium study confirms the presence of marked gastric dilation.

Figure 34-29 Gastric impressions by a polycystic liver. Two large extrinsic impressions (arrows) on the anterior aspect of the stomach could be mistaken for intramural lesions. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

on the duodenal bulb (Fig. 34-30), but even a normal common bile duct may occasionally produce a linear impression on the bulb. Extrinsic compression of the duodenum may also result from an enlarged gallbladder secondary to hydrops of the gallbladder, tumor, a pericholecystic abscess or other causes.

Hepatomegaly or anomalous lobes of the liver may cause leftward displacement of the duodenal bulb and sweep.⁵⁶ Duodenal displacement may be particularly marked when there is hypertrophy of the caudate lobe. Hepatic cysts and tumors and metastatic lymphadenopathy in the periportal region may also produce one or more extrinsic impressions on the duodenal bulb and sweep.

Masses in the right kidney or adrenal may cause an extrinsic indentation on the right posterolateral aspect of the descending duodenum.⁵⁷ Generalized renal enlargement secondary to hydronephrosis, multiple cysts, polycystic kidney disease, or renal cell carcinoma may also compress and displace the duodenum (Fig. 34-31). In other patients, anterior displacement of the duodenum may be caused by an enlarged right adrenal gland from Addison's disease or adrenal carcinoma.

The midportion of the descending duodenum is crossed anteriorly by the transverse colon. In approximately 3% of patients, there is an abnormally close positional relationship between these two structures, resulting in a mutual indentation.⁵⁸ Carcinoma of the right side of the colon, especially the hepatic flexure, can result in an extrinsic impression on the outer border of the descending duodenum.⁵⁹ This finding may be caused by adjacent adenopathy or by direct extension of tumor across the short fascial plane of the lateral reflection of the transverse mesocolon, which attaches the hepatic flexure of the colon to the lower portion of the descending duodenum.

Figure 34-30 Duodenal impression by a dilated common bile duct. The dilated duct produces a characteristic tubular impression (arrows) on the duodenum near the apex of the bulb. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-31 Duodenal impression by a polycystic right kidney. The duodenum is displaced to the left of the spine by the polycystic kidney. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Dilated vessels can also produce one or more extrinsic impressions on the outer wall of the duodenal bulb and sweep. These impressions may be caused by duodenal varices resulting from portal hypertension or by dilated arterial collateral pathways resulting from occlusion of the celiac axis or superior mesenteric artery.⁶⁰

Widening of the Duodenal Sweep

Although widening of the duodenal sweep on barium studies is often considered to be synonymous with an enlarged head of the pancreas, this finding is not always caused by pancreatic disease, so it must be interpreted with caution. There is great variation in the configuration of the duodenal sweep among normal patients, and slight degrees of widening are difficult to recognize with confidence. In heavy patients, the combination of a high transverse stomach and long vertical course of the descending duodenum can also create the erroneous impression of a widened sweep.

True widening of the duodenal sweep may be caused by pancreatic neoplasms or by benign pancreatic disease (e.g., pancreatitis, pancreatic pseudocysts; Figs. 34-32 and 34-33; see next section). There are numerous radiographic criteria for distinguishing benign and malignant pancreatic disease involving the duodenum, but this differentiation is often difficult on barium studies. When pancreatic abnormalities are suspected, CT or other cross-sectional imaging studies should therefore be performed for a more definitive diagnosis.

Widening of the duodenal sweep may also be caused by enlarged peripancreatic lymph nodes secondary to lymphoma, metastases, or various inflammatory conditions (Fig. 34-34).⁶¹ Depending on their location, mesenteric cysts or tumors may

Figure 34-32 Widening of the duodenal sweep by acute pancreatitis. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-33 Widening of the duodenal sweep by a pancreatic pseudocyst. Pancreatitis or pancreatic carcinoma could produce similar findings (see Fig. 34-32). (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-35 Widening of the duodenal sweep by a choledochal cyst. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-34 Widening of the duodenal sweep by peripancreatic lymphoma. Enlarged peripancreatic lymph nodes have produced a double contour on the medial border of the duodenum with associated spiculation. Pancreatitis or pancreatic carcinoma could produce similar findings (see Fig. 34-36). (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

produce similar findings. Rarely, dilated pancreaticoduodenal collateral vessels in patients with an occluded celiac axis or superior mesenteric artery can produce a smooth, concave impression on the medial aspect of the descending duodenum that simulates a mass in the head of the pancreas.

Retroperitoneal masses (primary or metastatic neoplasms or cysts) can also widen the duodenal sweep. Downward displacement of the third portion of the duodenum by an aortic aneurysm can produce a similar radiographic appearance. A choledochal cyst near the ampulla of Vater can result in generalized widening of the duodenal sweep (Fig. 34-35) or a localized impression near the papilla.

Pancreatic Diseases Affecting the Stomach and Duodenum

Before the advent of ultrasound, CT, and magnetic resonance imaging (MRI), alterations in the configuration and mucosal pattern of the antrum and duodenal sweep were carefully evaluated on barium studies as indirect signs of inflammatory or neoplastic disease involving the head of the pancreas. Although primarily of historical interest, the findings on upper GI barium studies may occasionally suggest otherwise unexpected pancreatic disease.

Enlargement of the head of the pancreas can produce a mass impression on the inner aspect of the duodenal sweep that

Figure 34-36 Duodenal involvement by pancreatic carcinoma. An enlarged pancreatic head produces a double contour on the medial border of the duodenal sweep. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

creates a double contour effect (Fig. 34-36). Another nonspecific sign, originally attributed to malignant disease, but probably more common in inflammatory disorders, is the so-called inverted 3 sign of Frostberg (Fig. 34-37). The central limb of the inverted 3 represents the point of fixation of the duodenal wall, where the pancreatic and common bile ducts insert into the papilla. The impressions above and below this point reflect tumor mass, edema of the major and minor papillae, or edema of the duodenal wall from adjacent pancreatitis. Pancreatitis or pancreatic tumor invading the duodenum may also be manifested by spiculation and tethering of the medial wall of the duodenum because of a desmoplastic reaction in the serosa (Fig. 34-38).

In advanced disease, duodenal involvement by pancreatitis, pancreatic pseudocysts, or pancreatic carcinoma may be manifested by the development of ulcers, cavities, or even pancreaticoduodenal fistulas. Pancreatitis, pseudocysts, or neoplasms involving the head of the pancreas may also produce a smooth area of extrinsic mass effect on the greater curvature of the gastric antrum, also known as the antral pad sign.⁶² Further infiltration of the stomach by the inflammatory process or tumor may result in an irregular gastric contour with spiculated, tethered mucosal folds on the greater curvature (Fig. 34-39). Similarly, disease involving the body or tail of the pancreas may be manifested by extrinsic compression, flattening, or spiculation of the posterior wall of the gastric fundus or body (Fig. 34-40A and B). When gastric involvement by pancreatic disease is suspected on barium studies, other imaging tests such as CT, MRI, or ultrasound should be performed for a more definitive diagnosis (Fig. 34-40C).

Figure 34-37 Inverted 3 sign of Frostberg. There is a widened duodenal sweep, with fixation of the duodenal wall at the papilla (arrow), producing the inverted 3 sign. This patient had acute pancreatitis, so the inverted 3 sign is not specific for pancreatic carcinoma.

Unusual Filling Defects

BEZOARS

A bezoar consists of an accumulated mass of ingested food within the gastric lumen. Phytobezoars (composed of undigested vegetable matter) have typically been associated with the eating of unripe persimmons, a fruit containing substances that coagulate on contact with gastric acid to produce a sticky, gelatinous material, which traps seeds, skin, and other foodstuffs, acting as the nidus for developing bezoars. Trichobezoars (composed of hair) occur predominantly in women who swallow their own hair, usually because of schizophrenia or other mental illness. The accumulated mass of hair can enlarge until it occupies the lumen of the entire stomach, often assuming the shape of that organ. A small percentage of bezoars, also known as trichophytobezoars, are composed of a combination of hair and vegetable matter.

Despite the classic association of gastric bezoars with vegetable matter and hair, the most common cause of this finding in modern radiology practice is gastroparesis in patients who have diabetes or are taking narcotic medications.⁶³ Because of the important role of gastric peristalsis in the mechanical breakdown of ingested food, patients with decreased or absent gastric peristalsis are at increased risk for developing bezoars. Less

Figure 34-38 Duodenal involvement by pancreatitis. There is an extrinsic impression on the medial border of the descending duodenum, with spiculated mucosal folds. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

frequently, gastric bezoars may also be found in patients with chronic gastric outlet obstruction secondary to scarring from peptic ulcer disease or other causes. Finally, bezoars may develop after partial gastrectomy or bariatric surgery in which the antrum and body of the stomach (the portions of the stomach responsible for gastric peristalsis) have been resected (Billroth I or II) or bypassed (Roux-en-Y gastric bypass).⁶³ Because there is little or no gastric peristalsis in the remaining gastric remnant or pouch, bezoars are more likely to develop in these patients. If a postoperative stricture develops at the gastroduodenal or gastrojejunal anastomosis, the risk of bezoar formation increases even further.⁶³

Symptoms of gastric bezoars, which result from the mechanical effects of the foreign body in the stomach, include crampy epigastric pain and a sense of fullness or heaviness in the upper abdomen.⁶³ Large bezoars may also cause symptoms of gastric outlet obstruction. Some bezoars may be chronic findings, necessitating endoscopy for mechanical breakdown of the mass of food matter in the stomach, but others may resolve rapidly (in <2 weeks) on conservative medical treatment.⁶³

A bezoar is sometimes visible on abdominal radiographs as a soft tissue mass floating in the stomach at the air-fluid interface (Fig. 34-41). Barium studies may show a conglomerate mass of debris with barium trapped in the interstices of the bezoar, producing a characteristic mottled appearance (Fig. 34-42).⁶³ With changes in patient position, many bezoars are freely movable within the gastric lumen.⁶³ Bezoars can also develop in the gastric remnant after a partial gastrectomy (Billroth I and II) or in the gastric pouch

Figure 34-39 Gastric involvement by pancreatitis. There is flattening, irregularity, and spiculation of the greater curvature of the antrum caused by extension of the inflammatory process to the stomach. Also note involvement of the proximal descending duodenum.

after gastric bypass (Roux-en-Y gastric bypass), especially when strictures develop at the gastroduodenal or gastrojejunal anastomosis, delaying emptying of ingested food. Occasionally, a bezoar may be unusually smooth, simulating an enormous gas bubble (Fig. 34-43). Bezoars are usually characterized on CT by inhomogeneous intraluminal masses that have a mottled appearance and are often seen floating at the air-fluid interface (Fig. 34-44).⁶⁴

FOREIGN BODIES

Foreign bodies may appear as radiolucent filling defects in the barium-filled stomach or duodenum. This appearance is produced by a variety of ingested substances, including food, pills, and nondigestible material.

HEMATOMAS

In patients with upper GI bleeding, blood clots may appear as one or more filling defects in the stomach or duodenum. Hemorrhage into the wall of the stomach secondary to a bleeding diathesis, anticoagulant therapy, or trauma can lead to the development of a large intramural gastric mass, usually involving the fundus.

Intramural duodenal hematomas are a recognized complication of blunt trauma to the abdomen. More than 80% of reported cases have occurred in children or young adults; child abuse is a major cause in infants and young children.⁶⁵ It is believed that the hematoma results from the duodenum being crushed between the anterior abdominal wall and vertebral column. Because the second and third portions of the duodenum are fixed in a retroperitoneal position, they are prone to this type of injury if enough force is applied to the anterior abdominal wall. When the mucosa is separated from the

(From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

loose submucosa, blood may dissect along submucosal compartments. Intramural duodenal hematomas may also be caused by a bleeding diathesis, anticoagulation, or endoscopic trauma.⁶⁶

Intramural duodenal hematomas may appear on barium studies as well-circumscribed intramural masses with discrete margins. Some degree of stenosis and obstruction is usually present (Fig. 34-45A). CT may reveal marked thickening of the duodenal wall in these patients.⁶⁷ CT is also helpful for differentiating duodenal perforation from a hematoma without perforation. The presence of perforation is indicated by extraluminal gas or extravasated contrast material in the right anterior pararenal space.⁶⁷ The right psoas margin may be obliterated because of associated retroperitoneal bleeding. A coil spring appearance has been described and, rarely, delayed rupture into the peritoneal or retroperitoneal space may occur. Although some patients

have discrete hematomas, others have diffuse bleeding in the duodenal wall, manifested by thickened, spiculated folds or thumbprinting (Fig. 34-45B).

INTRAGASTRIC AND INTRADUODENAL GALLSTONES

An intragastric gallstone is an extremely rare cause of a filling defect in the stomach. Gallstones may enter the stomach or duodenum in patients with cholecystogastric or cholecystoduodenal fistulas. Similar to other foreign bodies in the stomach, intragastric gallstones may cause mucosal irritation, ulceration, bleeding, perforation, and even obstruction. Erosion of a gallstone into the duodenal bulb may also cause gastric outlet obstruction (Bouveret's syndrome), a rare but life-threatening condition.^{68,69}

Figure 34-43 Gastric bezoar. The bezoar appears as a smooth filling defect in the stomach that could be mistaken for an enormous gas bubble. This patient was a model airplane builder who had been ingesting glue. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-42 Gastric bezoar. The bezoar is manifested by a conglomerate mass of debris with barium trapped in its interstices, producing a characteristic mottled appearance.

Figure 34-44 Gastric bezoar on CT. The bezoar is characterized on CT by an inhomogeneous intraluminal mass with a mottled gas pattern (arrows). This patient underwent a partial gastrectomy and now has a bezoar in the gastric remnant because of a stricture at the gastrojejunal anastomosis (not visualized on this image). (From Woodfield CA, Levine MS: *The postoperative stomach*. *Eur J Radiol* 53:341–352, 2005.)

Gastric Volvulus

Gastric volvulus is an uncommon acquired twist of the stomach on itself that can lead to obstruction or strangulation with potentially life-threatening gastric infarction. It is usually associated with a large defect in the diaphragm that allows all or part of the stomach to herniate into the thorax. Free upward movement of the stomach into the chest is normally limited by

various ligaments, which anchor the stomach within the abdomen. The most rigid point of attachment is the site at which the second portion of the duodenum assumes a retroperitoneal position, thus becoming fixed to the posterior abdominal wall. The gastrocolic and gastrolenal ligaments also

contribute to fixation of the stomach. Because of these points of anatomic fixation, torsion of the stomach may occur, with significant degrees of gastric herniation. Less frequently, gastric volvulus may be associated with eventration or paralysis of the diaphragm in the absence of a true hernia. Cases of idiopathic gastric volvulus without apparent cause have also been reported.

With small herniations, the proximal portion of the stomach enters the hernial sac first. Obstruction or strangulation almost

never occurs at this stage. As herniation progresses, the body and a variable portion of the antrum come to lie above the diaphragm, so the stomach can eventually become an entirely intrathoracic organ that is prone to a volvulus. The term *organo-axial volvulus* refers to rotation of the stomach upward around its long axis—a line connecting the cardia with the pylorus. In this condition, the antrum moves from an inferior to superior position, with the intrathoracic stomach located in the right hemithorax. In *mesenteroaxial volvulus*, however, the stomach rotates from right to left or left to right about the long axis of the gastrohepatic omentum (a line connecting the middle of the lesser curvature with the middle of the greater curvature), with the intrathoracic stomach usually located in the left hemithorax.⁷⁰

Patients with chronic gastric volvulus may be asymptomatic if there is no gastric outlet obstruction or vascular compromise. Other patients may develop postprandial pain or vomiting if there is partial gastric outlet obstruction.⁷¹ In contrast, an acute gastric volvulus may present as a surgical emergency if the vascular supply to the stomach is compromised. An acute volvulus should be suggested by the classic triad of violent retching with production of little vomitus, constant severe epigastric pain, and an inability to advance a nasogastric tube beyond the distal esophagus. Vascular occlusion causes gastric necrosis, perforation, and shock, with a mortality rate of approximately 30%.

The radiographic signs of gastric volvulus are characteristic. Chest radiographs may reveal an intrathoracic stomach with a double air-fluid level in the chest when the patient is upright. Barium studies may reveal inversion of the intrathoracic stomach, with the greater curvature above the lesser curvature, the cardia and pylorus positioned in close proximity, and downward pointing of the pylorus and duodenum (also described as an upside-down intrathoracic stomach; Fig. 34-46).⁷² Gastric volvulus may also be recognized on CT by the presence of an enlarged, twisted stomach in the thorax with identification of one or more sites of torsion.⁷³ Barium studies are useful for showing gastric outlet obstruction, whereas CT is useful for showing signs of ischemia.

Figure 34-45 Intramural duodenal bleeding. **A.** There is marked narrowing and compression of the distal descending duodenum (arrow) by a large hematoma in a young child who had been kicked in the abdomen by his father. **B.** In another patient who had been undergoing anticoagulant therapy for a prosthetic heart valve, there is thumbprinting of the distal duodenum due to extensive intramural hemorrhage. (**A** from Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996; **B** courtesy Richard L. Baron, MD, Pittsburgh.)

Figure 34-46 Gastric volvulus. This patient has an organoaxial volvulus of the stomach causing gastric outlet obstruction. The stomach is located above the diaphragm, with inversion of the greater curvature above the lesser curvature and downward pointing of the pylorus. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Gastroduodenal and Duodenojejunal Intussusceptions

Gastroduodenal and duodenojejunal intussusceptions are rare entities, usually associated with gastric or duodenal tumors that serve as the lead point for the intussusception. In gastroduodenal intussusception, characteristic radiographic signs include foreshortening and narrowing of the gastric antrum, converging or telescoping mucosal folds in the antrum or duodenum, prepyloric collar-shaped outpouchings, widening of the pyloric channel, a coil spring appearance of duodenal mucosal folds, and widening of the duodenum with an associated intraluminal mass.^{74,75} Similarly, duodenojejunal intussusception produces an intraluminal mass associated with a characteristic coil spring pattern.⁷⁶

Fistulas

GASTROCOLIC AND DUODENOCOLIC FISTULAS

Fistulous communications between the stomach and duodenum and other abdominal organs may occur as a complication of benign or malignant disease. In the past, gastrocolic fistulas usually resulted from primary carcinomas of the colon or stomach.⁷⁷ In today's pill-oriented society, however, benign greater curvature gastric ulcers caused by aspirin or other NSAIDs have become a more common cause of gastrocolic fistulas than malignant tumors.⁷⁸ Occasionally, these greater curvature ulcers may penetrate inferiorly via the gastrocolic ligament to the superior border of the transverse colon, which is almost always the site of the colonic end of the fistula (Fig. 34-47).

Figure 34-47 Gastrocolic fistula caused by a benign greater curvature ulcer. Upper GI study shows a giant ulcer (long arrows) on the greater curvature of the stomach, with barium entering a fistula (short arrow) that communicates with the superior border of the transverse colon. This patient had an aspirin-induced ulcer as the cause of the gastrocolic fistula. (From Levine MS, Kelly MR, Laufer I, et al: *Gastrocolic fistulae: The increasing role of aspirin*. Radiology 187:359–361, 1993.)

Malignant tumors causing gastrocolic (Fig. 34-48) or duodenocolic (Fig. 34-49) fistulas tend to be bulky, infiltrating lesions associated with a marked inflammatory reaction. These tumors apparently extend from the serosa of one viscus into the wall of another, followed by lumen to lumen necrosis. The presence of a fibrous stroma within the wall of a malignant fistula accounts for the length of these tracks and the relative separation of bowel loops.⁷⁷

Malignant gastrocolic fistulas are frequently demonstrated on barium enema examinations but are rarely detected on upper GI barium studies. Increased intraluminal pressure in the colon at the time of a barium enema examination may overcome the resistance of a rigid, nondistensible fistula, allowing passage of barium into the stomach. In contrast, intraluminal pressure in the stomach during an upper GI barium study may not be sufficient to overcome this resistance.⁷⁹

A fistulous communication between the stomach, jejunum, and colon (gastrojejunocolic fistula) or directly between the stomach and colon represents a serious complication of marginal ulceration after gastric surgery for peptic ulcer disease (Fig. 34-50).⁸⁰ Most patients with this condition have diarrhea and weight loss; pain, vomiting, and bleeding occur in one third to one half of cases. These patients have a high mortality rate, especially if diagnosis of the fistula is delayed.

Figure 34-48 Gastrocolic fistula caused by carcinoma of the splenic flexure. Barium enema shows an annular carcinoma of the splenic flexure, with barium entering the stomach via a gastrocolic fistula (arrow). (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*. 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-49 Duodenocolic fistula caused by carcinoma of the proximal transverse colon. Barium enema shows an annular carcinoma (curved arrow) of the proximal transverse colon, with barium entering the duodenum via a duodenocolic fistula (straight arrow). (From Vieta JO, Blanco R, Valentini GR: Malignant duodenocolic fistula: Report of two cases, each with one or more synchronous gastrointestinal cancers. *Dis Colon Rectum* 19:542–552, 1976.)

Figure 34-50 Gastrojejunal fistula. This patient had undergone a partial gastrectomy and gastrojejunostomy. There is a large anastomotic ulcer (arrow) at the gastrojejunostomy with filling of the jejunum and transverse colon via a gastrojejunal fistula. (From Thoeni RH, Hodgson JR, Scudamore HH: The roentgenologic diagnosis of gastrocolic and gastrojejunal fistulae. *AJR* 83:876–881, 1960.)

CHOLECYSTODUODENAL FISTULAS

Fistulas between the gallbladder and duodenum may be caused by acute cholecystitis (90%) or by severe peptic ulcer disease (6%). The remaining cases are caused by trauma or tumor. Acute cholecystitis usually results in the development of a cholecystoduodenal fistula, but the inflamed gallbladder can also perforate into the stomach, jejunum, or hepatic flexure of the colon. In patients with severe peptic ulcer disease, a penetrating duodenal or gastric ulcer can perforate into the gallbladder or bile duct.⁸¹ Regardless of the cause, abdominal radiographs often show gas in the biliary tree. On upper GI barium studies, barium may fill the cholecystoduodenal fistula (Fig. 34-51).

OTHER FISTULAS

Aortoduodenal fistulas can occur as a complication of abdominal aortic aneurysms or prosthetic vascular grafts. Pressure necrosis of the third portion of the duodenum, which is fixed and apposed to the anterior wall of an aortic aneurysm, can lead to digestion of the aortic wall by enteric secretions, with the development of an aortoduodenal fistula. Secondary fistulas result from pseudoaneurysm formation with erosion into the adherent duodenum or dehiscence of the suture line associated with leakage of intestinal contents through the duodenum, whose blood supply has been compromised at surgery. An

Figure 34-51 Cholecystoduodenal fistula. Barium study shows barium filling the gallbladder (long arrow) via a fistula (short arrow) from the descending duodenum. Also note thickened folds and decreased distensibility of the duodenum in this patient with a long-standing history of ulcer disease. The fistula presumably developed as a complication of a penetrating postbulbar duodenal ulcer.

Figure 34-52 Aortoduodenal fistulas. **A.** The fistula causes extrinsic compression of the third portion of the duodenum (*thin arrows*) and displacement of an adjacent loop of jejunum (*thick arrows*). No contrast medium is seen entering the fistula. **B.** In another patient with an aortic graft, extravasated water-soluble contrast medium from the distal duodenum is seen tracking between the graft and aorta (*arrows*). (**A** from Wyatt GM, Rauchway MI, Spitz HB: Roentgen findings in aortoenteric fistulae. *AJR* 126:714–722, 1976.)

Figure 34-53 Pneumoperitoneum caused by a perforated duodenal ulcer. **A.** Free intraperitoneal air is seen beneath the right hemidiaphragm (*arrows*). **B.** Study using a water-soluble contrast agent shows free extravasation of contrast agent from the duodenum into the right side of the peritoneal cavity. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

aortoduodenal fistula is often a fatal condition, characterized by abdominal pain, GI bleeding, and a palpable, pulsatile mass. Barium studies may demonstrate compression or displacement of the third portion of the duodenum by an extrinsic mass (Fig. 34-52A). Rarely, in patients with aortic grafts, the wall of the abdominal aorta may be outlined by extraluminal contrast medium tracking along the graft into the paraprosthesis space (Fig. 34-52B).⁸²

Fistulas between the duodenum and right kidney may occasionally develop as a complication of pyelonephritis, particularly tuberculous pyelonephritis. The pathologic mechanism is usually rupture of a perirenal abscess into the duodenum, which is best demonstrated on retrograde pyelography. Rarely,

a duodenal ulcer may penetrate into the right kidney, producing a duodenorenal fistula.

Gastric and Duodenal Perforation

The most frequent cause of pneumoperitoneum in patients with peritonitis is a perforated peptic ulcer, either a gastric ulcer or, more commonly, a duodenal ulcer (Fig. 34-53A). In approximately 30% of patients with perforated ulcers, however, there is no evidence of free intraperitoneal air on abdominal radiographs. The failure to demonstrate pneumoperitoneum is therefore of little value in excluding the possibility of a perforated ulcer. In general, the absence of gas in the stomach and

presence of gas in the small and large bowel should suggest a gastric perforation as the cause of pneumoperitoneum. Conversely, the absence of colonic gas and presence of a gastric air-fluid level and small bowel distention make a colonic perforation more likely. The findings on abdominal radiographs can be misleading, however, so a firm diagnosis of the site of perforation requires study with a water-soluble contrast agent (Fig. 34-53B).⁸³

Benign Gastric Emphysema

Gas in the wall of the stomach can be a sign of infection, ischemia, or increased intraluminal pressure, but benign gastric emphysema may occasionally be demonstrated in the absence of underlying disease.⁸⁴ Although pneumatosis cystoides intestinalis may also affect the wall of the stomach, this condition usually involves the small bowel or colon (see Chapter 12). Gastric emphysema is most commonly caused by severe vomiting or by endoscopy or other iatrogenic injury that allows gas in the lumen to dissect via mucosal rents into the wall of the stomach. Gastric emphysema is typically manifested on abdominal radiographs by linear collections of gas in the gastric wall (Fig. 34-54).

Benign gastric emphysema should be differentiated from a life-threatening condition, emphysematous gastritis, a rare fulminant form of gastritis associated with gas-forming infection. This condition is usually caused by ischemia, severe gastroenteritis, ingestions of caustic substances, and gastroduodenal surgery that compromises the vascular supply of the stomach. Emphysematous gastritis is characterized by cystic, bubbly collections of gas in the gastric wall that have a very different appearance than the linear intramural collections seen in gastric emphysema (see Chapter 12).

Figure 34-54 Benign gastric emphysema. Linear collections of gas are seen in the gastric wall as a complication of endoscopy. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Amyloidosis

Deposition of an amorphous, eosinophilic, extracellular, protein-polysaccharide complex of amyloid in the stomach can produce a broad spectrum of radiographic findings. Amyloid infiltration is sometimes associated with marked narrowing and rigidity of the wall of the stomach (especially the antrum), producing a linitis plastica appearance.⁸⁵ Generalized thickening of gastric folds can also occur (Fig. 34-55).

Cystic Fibrosis

Cystic fibrosis is sometimes manifested on barium studies by a thickened, coarse fold pattern in the duodenum (Fig. 34-56). Associated findings include nodular indentations on the duodenal wall, smudging or poor definition of the mucosal fold pattern, and redundancy, distortion, and kinking of the duodenal contour.^{86,87} These changes are usually confined to the first and second portions of the duodenum, but occasionally extend into the proximal jejunum. The cause of duodenal fold thickening in cystic fibrosis is uncertain. It has been postulated that lack of secretion of pancreatic bicarbonate results in inadequate buffering of gastric acid, causing irritation and inflammation of the duodenum in these patients.⁸⁷

Figure 34-55 Gastric involvement by amyloidosis. There are thickened, nodular folds in the stomach secondary to infiltration of the gastric wall by amyloidosis. (From Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

Figure 34-56 Duodenal involvement by cystic fibrosis. A and B. In both cases, a thickened, coarse fold pattern is seen in the duodenum. (A from Eisenberg RL: *Gastrointestinal Radiology: A Pattern Approach*, 3rd ed. Philadelphia, JB Lippincott, 1996.)

CHAPTER OUTLINE

Diagnostic Evaluation Following Gastric and Duodenal Surgery

Surgical Considerations for Peptic Ulcer Disease

Indications for Surgery

Surgical Procedures for Peptic Ulcer Disease

Surgical Procedures for Gastric Resection

Billroth I Procedure

Billroth II Procedure

Roux-en-Y Gastrojejunostomy

Identification of Postsurgical Anatomy on Imaging Studies

Complications After Gastric Resection

Surgical Considerations for Gastric and Duodenal Neoplasms

Surgery for Gastric Masses

Surgery for Duodenal Masses

Complications Following Gastric and Duodenal Surgery for Neoplasm

Surgery for Weight Loss

Roux-en-Y Gastric Bypass

Laparoscopic Adjustable Gastric Banding

Sleeve Gastrectomy

Biliopancreatic Diversion with Duodenal Switch

Gastric and duodenal operations are usually performed for peptic ulcer disease (PUD), benign or malignant gastric or duodenum masses, and the treatment of obesity. Imaging studies are often an integral part of the evaluation of patients following gastric or duodenal surgery. Radiologic evaluation of postoperative patients requires understanding of the operative procedures, appreciation of the expected postoperative appearance, and knowledge of potential complications. In the early postoperative setting, the radiologist is often asked to assess the postsurgical anatomy and evaluate for possible early postoperative complications such as leakage. In the late postoperative course, radiologic evaluation may be undertaken to evaluate for more delayed complications or symptoms of abdominal pain, nausea and vomiting, weight loss, and weight gain.

Gastroduodenal surgical procedures may include resection and/or bypass of portions of the intestinal tract. Treatment of PUD may involve some form of vagotomy, often in conjunction with a procedure to improve gastric emptying (pyloroplasty or antrectomy). Following distal gastric resection,

continuity of the gastrointestinal (GI) tract may be reestablished via a Billroth I gastroduodenostomy or gastrojejunostomy (Billroth II or Roux-en-Y gastrojejunostomy). For treatment of gastric neoplasms, gastrojejunostomy is favored over gastroduodenostomy because this allows for wider surgical margins. The most common bariatric procedures currently performed in the United States include Roux-en-Y gastric bypass, laparoscopic adjustable gastric banding, and sleeve gastrectomy (gastric sleeve).

This chapter provides an overview of the more common surgical procedures performed on the stomach and duodenum as well as the indications for surgery, approaches to the radiologic evaluation, expected postsurgical appearance, and possible complications. Radiologists need to have an understanding of the expected postoperative anatomy to assess for possible complications and diagnose recurrent disease.

Diagnostic Evaluation Following Gastric and Duodenal Surgery

The imaging approach in patients following gastric and duodenal surgery depends on the type of surgical procedure performed, postoperative time course, patient's clinical status, and patient's presenting symptoms. Fluoroscopic and computed tomography (CT) studies are usually performed to evaluate postoperative patients; both may occasionally be necessary to establish the most accurate diagnosis.

Fluoroscopic Studies and Upper Gastrointestinal Examinations. Following abdominal surgery, an overhead scout radiograph should be obtained prior to administration of contrast to assess for postoperative clips, a staples and/or suture lines. The pattern of sutures and staples may help determine the surgical procedure performed if the patient history is unreliable. Also, surgical material should be identified prior to the administration of oral contrast so that radiopaque surgical material is not later mistaken for a small leak. In the early postoperative course, drains and abnormal gas collections may be assessed. Any expected or inadvertent indwelling surgical foreign body (e.g., gastric band device) should also be assessed on the scout radiograph.

In patients following gastric and/or duodenal surgery, the postoperative anatomy should be evaluated at the onset of the fluoroscopic procedure. Because each patient has unique surgical variations, a detailed, cookbook-style upper gastrointestinal examination (UGI) protocol for position changes during the study and required exposures does not tend to apply. Studies must be modified based on the surgical anatomy. Optimal patient positioning to evaluate an anastomosis is variable, depending on the type of surgical procedure

performed. The postoperative anatomy involving the stomach or duodenum should be evaluated prior to proceeding to other portions of the planned examination (e.g., assessment of esophageal motility or esophageal pathology). The initial contrast bolus should be observed fluoroscopically through the resected, oversewn, banded, sutured, or stapled sites and promptly imaged before there is contrast opacification of overlapping structures.

In the early postoperative setting, a UGI should be performed initially using water-soluble contrast agents to assess for possible postoperative leak because water-soluble contrast agents have no known damaging effects when extravasated into the peritoneal cavity or mediastinum.^{1,2} If no leak is identified with water-soluble contrast, barium should be administered. Barium may detect more subtle leaks and other complications.^{1,2} If the study is performed in the late postoperative course and a leak is not suspected, barium may be initially administered.

Single-contrast technique may be preferable to assess the postoperative anatomy, including any surgical anastomosis, and to evaluate for possible fistulas or staple line dehiscence following gastric surgery. In addition, supine patient positioning may be necessary and preferable in the debilitated or early postoperative patient. Double-contrast studies may provide more optimal assessment of mucosal detail, but may be difficult to perform in the postoperative patient because of diminished patient mobility or cooperation.³ Also, a patulous gastrojejunal or gastroduodenal anastomosis (gastric outlet) may preclude optimal gaseous distention of a gastric pouch or remnant. Intravenous (IV) glucagon administration may help slow the passage of barium and air through the gastric remnant and therefore allow for more optimal distention.⁴

Computed Tomography. Computed tomography (CT) may also be performed to assess for postoperative complications. CT can provide detail about the overall anatomy in the abdomen and pelvis, evaluate the bowel in its entirety, and assess the extent of any postoperative fluid collections.

Abdominopelvic CT following gastric and duodenal surgery is ideally performed following the administration of positive oral and IV contrast. Positive oral contrast helps depict the proximal GI anatomy on CT. As with fluoroscopic studies, water-soluble oral contrast should be administered rather than barium in the early postoperative course or if perforation is a consideration. Oral contrast may be administered at intervals prior to the CT study; however, it should also be administered immediately prior to image acquisition to opacify the residual stomach.

Nuclear Medicine. Scintigraphic studies may be of benefit for patients following gastric and/or duodenal surgery to assess for possible motility problems or postgastrectomy syndromes, including GI stasis and dumping syndrome. Radiolabeled solids or liquids can be used to evaluate gastric emptying.⁵ A time-activity curve can be applied to determine the emptying time of the stomach.

Endoscopy. Endoscopy may be useful to assess a surgical anastomosis and evaluate for possible complications such as marginal ulcer disease. Endoscopy may be of particular benefit for diagnosing inflammatory conditions such

as bile reflux gastritis and for diagnosing early tumor recurrence.^{6,7}

Surgical Considerations for Peptic Ulcer Disease

There has been a decline in the number of operative procedures performed for peptic ulcer disease over the last 3 decades.⁸ This is partly because of increased use of medications such as histamine-2 blockers (H2 blockers), proton pump inhibitors (PPIs), and agents to protect the gastric mucosa, including sucralfate and prostaglandin analogues. Identification and treatment of *Helicobacter pylori* infection has been overwhelmingly beneficial, as has the understanding of the role of nonsteroidal anti-inflammatory drugs (NSAIDs) in peptic ulcer disease.⁹ Surgical therapy is usually reserved for patients with severe and emergent complications of ulcer disease. The most common complications of peptic disease, in decreasing order of frequency, are bleeding, perforation, and obstruction. Most peptic ulcer related deaths in the United States are caused by bleeding,^{8,10} which may include melena and/or hematemesis. Patients with perforation may present with an acute abdomen.⁸ A detailed discussion of peptic ulcer disease and its manifestations may be found elsewhere (see Chapter 29).

INDICATIONS FOR SURGERY

Indications for surgery in the setting of peptic ulcer disease may include perforation, bleeding, gastric or duodenal obstruction, intractability, and nonhealing ulcers.^{8,11-14}

Perforation. In patients with acute ulcer perforation, the ulcer may simply be oversewn. In younger patients in particular, simple closure is often successful, with less than 20% chance of recurrence. However, a simple patch may be inadequate for older patients, and more definitive therapy may entail resection.¹⁵

Bleeding. In approximately 70% of cases of major bleeding from PUD, the bleeding stops spontaneously.¹⁵ Surgery may be necessary because of shock or continued bleeding, despite optimal medical management and endoscopic therapy. Surgical management may consist of vagotomy with pyloroplasty or vagotomy with antrectomy (see later).¹⁴

Obstruction. Gastric outlet or duodenal obstruction occurs in less than 10% of patients with PUD.¹⁴ This typically requires resection, usually with a gastrojejunostomy.

Nonhealing Ulcers. Patients with ulcers that fail to heal despite 12 to 15 weeks of optimal medication may be surgical candidates. As many as 10% to 15% of duodenal ulcers do not heal after a 6-week course of high-dose H2 blockers and PPIs, and in 15% to 30% of ulcers that initially heal with medical treatment, relapse occurs.^{14,16} In the case of refractory gastric ulcers, underlying gastric cancer must always be a consideration. In patients with intractable ulcers, elective surgical intervention is preferable, with a lower recurrence rate as compared with more urgent or emergent surgical management.

SURGICAL PROCEDURES FOR PEPTIC ULCER DISEASE

The physiologic basis of surgery for PUD includes methods to decrease secretion of hydrochloric acid from parietal cells located in the body and fundus of the stomach and to remove the portion of the gastric mucosa that is most predisposed to ulcers. Typically, surgical management of peptic ulcer disease includes truncal vagotomy with pyloroplasty, vagotomy with distal gastrectomy, or a highly selective vagotomy (HSV). Overall, vagotomy with distal gastrectomy results in the lowest ulcer recurrence rates; however, this has increased morbidity as compared with other treatment options.^{12,14}

Patients undergoing surgery for peptic ulcer disease may alternatively undergo simple oversewing of a bleeding ulcer or a simple patch of a perforated ulcer.^{8,9} UGI may be performed following this surgery to assess for leaks. A simple patch of a perforated ulcer may appear as a localized filling defect or may simulate an ulcer on UGI.¹⁷

Vagotomy

Vagotomy decreases total acid secretion. Also, parietal cell response to gastrin and other stimulants decreases after vagotomy.

Truncal vagotomy requires complete transection of the anterior and posterior vagus nerve trunk and results in denervation of the stomach, liver, gallbladder, pancreas, small intestines, and proximal large intestine. Loss of the antropyloric mechanism results in gastric stasis, and a pyloroplasty, gastroduodenostomy, or gastrojejunostomy must be performed to improve gastric drainage.⁸ Gastrojejunostomy is the preferred choice for patients with gastric outlet obstruction or a severely diseased duodenum. Truncal vagotomy has the side effects of dumping or diarrhea in 10% of patients.⁸

Highly selective vagotomy (HSV),¹ also called parietal cell vagotomy or proximal gastric vagotomy, is a relatively safe procedure with minimal side effects that decreases total acid secretion by 75%.⁸ With HSV, the vagal nerve supply to the proximal 2/3 to 3/4 of the stomach (parietal cell location) is severed with preservation of the distal branches to the antrum and pylorus. The antropyloric mechanism remains intact and the innervation to remaining abdominal viscera is preserved, minimizing gastrointestinal side effects.⁸ This operation does not alter gastric emptying and therefore does not require a drainage procedure, gastric resection, or an anastomosis. Elective HSV may be a preferred treatment for refractory PUD in the absence of gastric outlet obstruction.¹⁸ However, overall elective HSV for treatment of PUD has largely been replaced by long-term PPI treatment.⁸ Also, patients with pyloric and prepyloric ulcers have higher ulcer recurrence rates after HSV than those with duodenal ulcers alone. In this setting, a truncal vagotomy with antrectomy may be preferable.

Radiography or CT studies following vagotomy may reveal multiple clips in the expected distribution of the vagus nerve and/or its branches.

Pyloroplasty

Pyloroplasty consists of reconstructing the pyloric channel to increase its diameter and improve gastric emptying.

Following truncal vagotomy, impairment of gastric tone and interruption of the antropyloric mechanism result in gastric stasis, and a gastric drainage procedure is required. Pyloroplasty is relatively easy for the surgeon to perform, with less necessary dissection as compared with antrectomy. It also avoids surgical difficulties that may arise with a duodenal stump following antrectomy, and continuity of the GI tract is not altered.⁹

Heineke-Mikulicz Pyloroplasty. A Heineke-Mikulicz pyloroplasty consists of a longitudinal incision from the distal antrum to the proximal duodenum through the pylorus, followed by a transverse closure (essentially parallel to the base of the duodenal bulb) to increase the diameter of the pyloric channel.

Finney Pyloroplasty. A Finney pyloroplasty may be preferred when a longer incision of the duodenum is required to control bleeding or with scarring of the pylorus and duodenal bulb. A Finney pyloroplasty is essentially a side-to-side gastroduodenostomy. An incision is made along the greater curvature of the distal stomach, extending through the pylorus along the medial aspect of the duodenum. An inverted U-shaped incision is made, opening the pyloric channel.

Jaboulay Pyloroplasty. A Jaboulay pyloroplasty is actually a gastroduodenostomy between the antrum and duodenum. The pylorus is not technically incised. This results in a large opening between the distal stomach and duodenum and avoids any inflammatory process in the pyloric area.

Antrectomy

An antrectomy will remove the source of gastrin and prevent gastric stasis. When performed in combination with truncal vagotomy, antrectomy is the gold standard for reducing acid secretion, with the lowest recurrence rates when compared to vagotomy with pyloroplasty and HSV alone. Antral resection with vagotomy is the most definitive operation for treating ulcer disease. Ulcer recurrence following antrectomy is less than 1%, whereas following vagotomy and pyloroplasty, recurrence rates range from 4% to 27%, and recurrence rates following HSV range from 4% to 11%.¹⁹⁻²³ However, low recurrence rates must be weighed against postgastrectomy and postvagotomy complications that occur in up to 20% of patients; these may include diarrhea, dumping, bile reflux gastritis, weight loss, and metabolic consequences.^{9,23,24} Also, there is increased morbidity and mortality risk with gastric resection as compared with HSV alone or vagotomy with pyloroplasty. Antrectomy with vagotomy may be most beneficial for patients with complicated PUD (e.g., patients with bleeding, obstruction, nonhealing, and/or recurrent ulcers).

Antrectomy typically leaves enough of a gastric remnant to allow for maintenance of adequate nutrition, but a bowel anastomosis is necessary. Antrectomy with Billroth I reconstruction (gastroduodenostomy) is the most physiologic anastomosis because it restores normal bowel continuity. Alternatively, a Billroth II reconstruction (gastrojejunostomy) may be performed. A loop of jejunum is brought up to the greater curvature side of the gastric remnant. The duodenal stump must be closed, and this may be technically challenging, especially if the duodenum is diseased.⁹

Surgical Procedures for Gastric Resection

Partial gastrectomy may consist of resection of the antrum, distal two thirds of the stomach, distal 60% of the stomach, or high subtotal gastrectomy, depending on the type of disease (e.g., ulcer, cancer) and its location. Following gastric surgery, GI tract continuity requires an anastomosis and distal partial gastrectomy, and the distal partial gastrectomy procedure is named according to the type of anastomosis between the gastric remnant and small intestine, regardless of the extent of gastric resection. Surgical procedures to restore continuity following distal gastric resection include Billroth I and II procedures and Roux-en-Y gastrojejunostomy.

Following antrectomy for peptic ulcer disease, GI continuity is reestablished with a Billroth I gastroduodenostomy or Billroth II gastrojejunostomy. An additional choice for the gastrojejunostomy may be a Roux-en-Y gastrojejunostomy. However, when antrectomy is performed for ulcer disease, there is typically a large gastric remnant (60% to 70% of the stomach); Roux-en-Y gastrojejunostomy should be avoided in this setting. In the presence of a large gastric remnant, Roux-en-Y construction will predispose to gastric stasis and marginal ulcers.⁸ Distal gastrectomy for gastric neoplasm typically results in a smaller gastric remnant, and Roux-en-Y gastrojejunostomy may be preferable to prevent biliopancreatic secretions and duodenal contents from entering the gastric remnant and esophagus.

BILLROTH I PROCEDURE

The Billroth I procedure consists of antrectomy with a gastroduodenal anastomosis (Fig. 35-1). The distal gastric remnant is anastomosed to the end of the proximal duodenum. GI tract continuity is restored with preservation of the duodenal passage. Constructing the gastroduodenal anastomosis to approximate the size of the pylorus helps delay gastric emptying and reduce problems with postgastrectomy dumping. Because of anastomotic requirements, gastroduodenostomy may only be performed following antrectomy. For more significant gastric resections, a gastrojejunostomy is necessary. Also, in patients with gastric outlet obstruction caused by PUD, gastrojejunostomy is preferable to gastroduodenostomy.

BILLROTH II PROCEDURE

The classic Billroth II procedure is a distal gastrectomy with a loop-type gastrojejunostomy (Fig. 35-2). The gastric remnant is anastomosed to the side of the proximal jejunum. An area of the jejunum approximately 12 to 15 cm distal to the ligament of Treitz (the first or second loop of jejunum) is typically chosen and is brought to the greater curvature of the gastric remnant. The anastomosis may involve the entire end or a portion of the gastric remnant; an anastomosis along the dependent greater curvature of the gastric remnant facilitates gastric emptying.²⁵ This then creates a proximal or afferent loop consisting of the oversewn duodenal stump and the most proximal jejunum, which carry the biliopancreatic secretions. There is then a distal or efferent loop extending downstream, carrying gastric contents distally. The gastrojejunostomy may be anterior to the transverse colon (antecolic) or posterior to the transverse colon (retrocolic). A retrocolic configuration

Figure 35-1 Billroth I. **A.** There is an antrectomy with an end-to-end gastroduodenostomy. **B.** UGI image shows slight foreshortening of the stomach following antrectomy. No normal pylorus is seen, and there has been a gastroduodenostomy. Also note surgical clips from truncal vagotomy (arrow). **D**, duodenum.

allows for a shorter afferent loop, which may result in fewer postoperative complications.⁴

ROUX-EN-Y GASTROJEJUNOSTOMY

With a Roux-en-Y gastrojejunostomy, the jejunum is transected, and the proximal end of the jejunum (the Roux limb) is anastomosed to the gastric remnant, usually end-to-side (Fig. 35-3). The small bowel may be brought up anterior or posterior to the transverse colon (antecolic or retrocolic, respectively). When the small bowel is brought up posterior to the transverse colon, an opening is made in the transverse mesocolon, which must be repaired. For malignancy, an antecolic location may be

Figure 35-2 Billroth II. **A.** There is an antrectomy with loop-type gastrojejunostomy. The proximal jejunum is brought up and anastomosed along the dependent greater curvature of the gastric remnant. This creates a proximal afferent loop (including the oversewn duodenum) carrying the pancreatic and biliary secretions toward the stomach and a distal efferent loop, which extends downstream, carrying gastric contents distally. **B.** UGI spot image and overhead radiograph (**C**) show distal gastrectomy with a patent gastrojejunostomy (arrow). Contrast is opacifying the stomach remnant (S) and jejunum (J). There is a small amount of contrast refluxed into the oversewn duodenum (D). **D.** Axial contrast-enhanced CT scan shows the stomach remnant (S) anastomosed to the jejunum (J) with a clip in the vicinity of the anastomosis (arrow).

preferable to minimize obstruction caused by tumor recurrence in the lesser sac.²⁶ The end of the proximal jejunal segment is then anastomosed to the more distal jejunum at least 40 to 60 cm from the gastrojejunal anastomosis. This procedure diverts duodenal contents and biliopancreatic secretions away from the stomach and prevents bile reflux into the stomach, which may help minimize bile reflux gastritis.²⁷ However, transection of the small bowel alters intestinal motility, and there may be impaired emptying of the Roux limb as a consequence. A Roux-en-Y gastrojejunostomy should ideally be performed

in the setting of a small gastric remnant to minimize marginal ulcer disease and problems with gastric stasis.

IDENTIFICATION OF POSTSURGICAL ANATOMY ON IMAGING STUDIES

The postoperative anatomy following gastroduodenostomy or gastrojejunostomy may be evaluated with UGI or CT. Procedures for distal gastrectomy should be readily identified on UGI. Along with foreshortening of the stomach caused by

Figure 35-3 Roux-en-Y gastrojejunostomy. There is a distal gastrectomy with gastrojejunostomy. The jejunum is transected and anastomosed to the gastric remnant with an additional left midabdominal jejunostomy.

distal resection, there is absence of a normal pylorus in a gastroduodenostomy, typically with an end-to-end anastomosis (see Fig. 35-1). This may be difficult or impossible to identify on CT if the gastric remnant consists of most of the stomach, and surgical clips or sutures are not present. In the setting of a gastrojejunostomy, jejunal loops will be contiguous with the gastric remnant. On CT, a jejunal limb will be contiguous with the gastric remnant and can be followed through its antecolic or retrocolic course. Sutures or staples may be seen along the proximal duodenal stump. On UGI, the gastrojejunal anastomosis should appear widely patent (see Fig. 35-2). A portion of the cut end of the stomach may be oversewn or inverted to restrict the size of the stoma, which can produce deformity and plication defects around the margins of the anastomosis.¹⁷ Plication defects can be mistaken for leaks, ulcers, or recurrent tumor if not appreciated.⁴ Unlike a plication defect, there will be persistent contrast in a leak following passage of the bolus. The adjacent gastric folds will appear thickened and lobulated in the case of recurrent ulcer or tumor as compared with postoperative deformity. Comparison with a baseline postoperative UGI may help clarify the process. Alternatively, endoscopy may be necessary.

COMPLICATIONS AFTER GASTRIC RESECTION

Metabolic Problems

Anemia may be a consequence of gastric resection. Iron deficiency is the most common cause, but vitamin B₁₂ or folate deficiency may also occur. Contributing factors may include malabsorption, inadequate oral intake, and chronic bleeding. Iron deficiency anemia may be related to rapid passage through the proximal jejunum, with resultant decreased iron absorption. Also, decreased acid and pepsin may limit the conversion of organic iron to inorganic iron (absorbable by the GI tract).²⁸ Loss of intrinsic factor production in the stomach can lead to vitamin B₁₂ deficiency.

Figure 35-4 Anastomotic leak following Billroth II gastrojejunostomy. This UGI image shows Billroth II anatomy. There are thickened folds in the anastomotic region secondary to postoperative edema in this recent postoperative patient. There is extravasation of contrast material from the gastrojejunal anastomosis, with the leak (arrows) extending toward an amorphous extraluminal contrast collection (C). J, jejunum; S, stomach remnant.

Gastric surgery may also disturb calcium and vitamin D metabolism, resulting in metabolic bone disease. Calcium is absorbed in the duodenum, which is bypassed in a gastrojejunostomy. Also, fat malabsorption can occur because of bacterial overgrowth, insufficient mixing of food with digestive enzymes, or afferent loop syndrome. This can result in decreased absorption of fat-soluble vitamin D.⁸

Postoperative Leak

Anastomotic leak or breakdown of a suture line can occur at any anastomosis in up to 5% of patients.²⁹ Following a Billroth I procedure, leaks may occur at the gastroduodenal anastomosis. With a Billroth II, leaks may occur at the gastrojejunostomy or from the oversewn duodenal stump. With a Roux-en-Y reconstruction, leakage may also occur at these sites or, rarely, at the jejunojejunal anastomosis.

Water-soluble contrast should be used on UGIs if leakage is a concern. Extravasation of contrast material may be seen, with contrast opacifying a track or collection or coursing freely in the peritoneal cavity (Fig. 35-4). A fistula may be seen with contrast opacifying another structure. Any postoperative drain should be carefully evaluated because opacification of a drain may be the only manifestation of a leak on UGI. CT may be necessary to determine the extent and location of collections and abscesses more definitively and to assess for leakage from the oversewn duodenum (Fig. 35-5). Dehiscence of the duodenal stump suture line may be difficult to diagnose with imaging studies and can be a serious complication, resulting in leakage of bile and pancreatic sections into the peritoneal cavity.²⁶ The duodenal stump may be difficult to opacify in retrograde fashion (antepertaltic) on UGI. As a result, a fluoroscopic study that does not demonstrate an anastomotic leak following gastrojejunostomy does not exclude the presence of leakage,

Figure 35-5 Duodenal stump leak after Billroth II. **A.** Axial contrast-enhanced CT scan shows the stomach remnant (S) anastomosed to the jejunum (J) with a clip (black arrow) in the vicinity of the oversewn duodenal stump (D). There is a fluid collection containing gas anterior to the duodenal stump (white arrows). Also note foci of adjacent extraluminal gas. **B.** Supine UGI image shows the Billroth II anatomy with a small amount of reflux in the afferent limb opacifying the duodenal stump (D). There is an amorphous collection (arrows) of contrast, confirming a duodenal stump leak.

particularly from the oversewn duodenal stump.³⁰ CT may reveal complex fluid or gas collections in the vicinity of the duodenal stump (see Fig. 35-5), in the subhepatic or peripancreatic space, or findings of peritonitis.²⁶

Gastric Stasis

Stasis in a gastric remnant can result in postprandial bloating, vomiting, abdominal pain, and weight loss. Gastric stasis occurs without evidence of mechanical intestinal obstruction or anastomotic narrowing in up to 25% of patients, depending on the type of reconstruction that was performed.³¹ Ineffective gastric emptying, impaired bowel motility, and alkaline reflux gastritis can contribute to gastric stasis.³² UGI should reveal a patent anastomosis without obstruction. Nuclear medicine studies may be of benefit to assess gastric emptying.⁵ Severe gastric stasis may require surgical revision with repositioning of the anastomosis or total gastrectomy.

Roux Syndrome

Roux syndrome, or Roux stasis syndrome, may occur following distal gastrectomy with a Roux-en-Y gastrojejunostomy. With this syndrome, patients have an atonic stomach with delayed emptying of the gastric remnant and Roux limb without evidence of obstruction.^{8,32} This represents a motility abnormality rather than a mechanical problem. Patients may present with vomiting, epigastric pain, and weight loss.

On UGI, there is dilation of the gastric remnant with delayed emptying. The efferent limb is typically dilated, without evidence of mechanical obstruction. It is important to assess the anastomosis to make sure that an anastomotic stricture is not a contributing factor. A gastric emptying nuclear medicine scan may also show delayed solid and/or liquid emptying. GI motility testing shows abnormal motility in the Roux limb, with propulsive activity toward the stomach rather than away from the stomach.⁸ Promotility medications may be beneficial.

Obstruction

Gastric outlet or small bowel obstruction can be an early or late postoperative complication following ulcer surgery. Obstruction may be caused by postoperative edema or hematoma in the

Figure 35-6 Stomal stenosis following Billroth II. This UGI image obtained with the patient drinking in the upright position shows stenosis of the gastrojejunal anastomosis (arrow). Also note the outpouchings adjacent to the anastomosis caused by postsurgical deformity and redundancy. There are no thickened, lobulated folds to suggest ulcers. J, jejunum; S, stomach remnant.

early postoperative course. In contrast, late postoperative obstruction can be caused by anastomotic strictures, with or without stomal ulcers, adhesive disease, or internal hernias.³⁰ UGI may reveal an anastomotic stricture with gastric outlet obstruction (Fig. 35-6). The patient should be positioned at

fluoroscopy so that the anastomosis is viewed in profile, without overlapping structures, to optimally assess anastomotic width and height. Endoscopic treatment and balloon dilation of strictures may be beneficial in some patients.³³

Bezoar Formation

A bezoar is a potential complication of subtotal gastrectomy. A bezoar may form in a gastric remnant as a result of decreased peristalsis and absence of gastric acid, especially when a vagotomy has been performed. Retained ingested material can coalesce to become a large masslike conglomerate. On UGI and CT, this appears as a large mottled mass within the gastric remnant. Contrast material and gas trapped within the interstices of the mass may help establish the correct diagnosis (Fig. 35-7). Also, bezoars are usually mobile, allowing for distinction from a gastric tumor. A bezoar can lead to gastric outlet obstruction and occasionally small bowel obstruction if the bezoar passes into the jejunum. Bezoars may be successfully treated endoscopically, but surgical intervention may be necessary, especially with an associated obstruction.

Dumping Syndrome

Dumping is a phenomenon caused by destruction or bypass of the pyloric sphincter (as with pyloroplasty or antrectomy) with rapid gastric emptying; however, other factors likely play a role.⁸ Patients with early dumping syndrome experience vasomotor

and cardiovascular symptoms, including tachycardia, dizziness, diaphoresis, weakness, nausea, abdominal cramping, diarrhea, and the need to lie down after eating.^{18,32,34} Postprandial symptoms may be severe and disabling. High-carbohydrate food may precipitate the worst attacks. A rapid influx of sugars into the proximal jejunum may cause a strong osmotic effect, drawing fluid into the bowel.

Crampy abdominal pain and distention are not uncommon, and diarrhea often follows. Early dumping occurs 15 to 20 minutes after a meal in 5% to 50% of patients, depending on the specific operation.³⁵ Clinically significant dumping occurs in 5% to 10% of patients after pyloroplasty or distal gastrectomy.⁸ Because of the abdominal pain associated with eating, patients tend to lose weight and become malnourished.³⁶

UGI in early dumping syndrome may reveal very rapid transit time with rapid opacification of the colon. Conservative therapy for dumping syndrome consists of dietary management; most patients improve with dietary changes over time.⁸ A somatostatin analogue may be beneficial.³⁶ Surgical management may be necessary in a small percentage of patients, but the results of surgery for dumping symptoms are variable and unpredictable.^{8,35}

Late dumping, also called postprandial (reactive) hypoglycemia, occurs 2 to 4 hours after a meal and may have similar vasomotor symptoms, but does not typically have the associated GI symptoms.³⁶ This can be alleviated by the administration of carbohydrates.⁸

Stomal and Anastomotic Ulceration

Recurrent ulcers following gastric surgery for PUD occur at or near the anastomosis, usually on the duodenal or jejunal side of the anastomosis for a Billroth I or II procedure, respectively.³⁷ In a Billroth II, the efferent loop is more commonly involved than the afferent loop.¹⁷ These ulcers are referred to as stomal, marginal, or postanastomotic ulcers; they occur primarily following inadequate gastric resection with a retained segment of antrum or because of a hypersecretory state or gastrinoma. In the setting of a Roux-en-Y gastrojejunostomy for PUD, a large gastric remnant predisposes to marginal ulcers.

UGI may reveal an ulcer crater with surrounding edema (Fig. 35-8). Stomal ulcers may be difficult to diagnose on UGI studies because of opacification of overlapping structures, and it may be difficult to distinguish barium trapping in distorted folds and plication defects from an ulcer.⁴ A baseline postoperative comparison study may be most beneficial to make this distinction. Secondary signs of ulcers may include narrowing at the anastomosis with thickened, edematous, and masslike folds. UGI findings may be less reliable compared with endoscopy,^{6,38} but contrast studies are increasingly necessary when endoscopy is limited or difficult.³⁰ If recurrent ulcers fail to respond to medical management, total gastrectomy may be necessary.

Jejunogastric Intussusception

Intussusception may occur in the vicinity of any anastomosis. Jejunogastric intussusception is a rare complication following gastrojejunostomy, with a reported incidence of 0.1%; the efferent loop intussuscepts into the stomach more often than the afferent loop.³⁹ Prolapse may occur in an antegrade or retrograde direction. Retrograde migration of the jejunal segment into the gastric remnant can be acute, chronic, or

Figure 35-7 Bezoar following Billroth I. This supine UGI image shows a gastroduodenostomy. Also note clips from a prior vagotomy (arrow). There is a conglomerate mass in the gastric remnant, with contrast in the interstices consistent with a bezoar. Gastric atony and diminished gastric drainage contribute to bezoar formation. D, duodenum.

Figure 35-8 Billroth II with a recurrent ulcer. This upright UGI image shows a gastrojejunostomy with edema in the vicinity of the anastomosis. The gastric remnant is dilated and contains a large amount of fluid and debris. There is a focal ulcer crater in the jejunum adjacent to the anastomosis (arrows) with surrounding edema and fold thickening. J, jejunum.

Figure 35-9 Jejuno-gastric intussusception following Billroth II. A right lateral UGI image shows a dilated gastric remnant with a filling defect in the gastric remnant near the gastrojejunal anastomosis caused by retrograde migration of the jejunum into the stomach. Jejunal folds are seen within the gastric remnant (arrows). J, jejunum.

intermittent and can result in partial or complete gastric outlet obstruction.^{30,40} On CT, the proximal jejunum, along with the adjacent mesenteric fat and vessels, can be seen within the lumen of the gastric remnant.⁴¹ On UGI, contrast can be seen outlining the jejunal folds within the gastric remnant, producing a coil spring appearance (Fig. 35-9). A gastrojejunal intussusception may be manifested by narrowing of the distal gastric remnant with a coil spring filling defect in the adjacent proximal jejunum.

Afferent Loop Syndrome

Following gastrojejunostomy, the afferent loop (duodenal stump containing biliopancreatic secretions) may become dilated, which can lead to abdominal pain, nausea, vomiting, postprandial fullness, and, rarely, obstructive jaundice. This has been called *afferent loop syndrome*; it occurs in less than 1% of patients.⁴ Afferent loop syndrome may be caused by blockage of this limb and may occur with adhesions, kinking or fibrosis near the anastomosis, internal hernias, or volvulus.⁴² Partial obstruction of the afferent loop results in luminal dilation with accumulation of biliary, pancreatic, and duodenal secretions. Acute complete obstruction may also occur. Afferent loop syndrome can also be due to preferential flow of ingested contents into the afferent limb (retrograde) rather than into the efferent limb.

Diagnosis of afferent loop syndrome caused by obstruction may be best made on CT. CT reveals a dilated, fluid-filled afferent loop (Fig. 35-10) and may also reveal the cause of

obstruction.^{42,43} On UGI, the obstructed afferent loop may not be opacified. The diagnosis may be inferred by the absence of opacification of the afferent limb and mass effect on the opacified efferent limb by the fluid-filled, unopacified afferent segment. However, lack of opacification of the afferent limb occurs in up to 20% of all patients following gastrojejunostomy, so lack of opacification by itself is not a reliable indicator of afferent loop syndrome.⁴⁴ Afferent loop syndrome can also be due to preferential flow of ingested contents into a dilated afferent limb rather than the efferent limb, and this can be readily identified with UGI (see Fig. 35-10C). In afferent loop syndrome, hepatobiliary scintigraphy reveals retention in the dilated biliopancreatic segment.

Bile Reflux Gastritis, Chronic Remnant Gastritis

A common complication following gastric surgery is chronic gastritis. Bile reflux gastritis occurs in 5% to 15% of patients following partial gastrectomy.^{36,45} Without an intact pylorus, chronic reflux of bile and pancreatic secretions into the gastric remnant can result in inflammatory change in the residual stomach. Following resection of the pylorus, most patients have bile in the stomach, with some degree of inflammation on endoscopic examination, and therefore many patients remain asymptomatic in the setting of bile reflux.⁸ However, a subset of patients will have bile reflux gastritis and present with nausea, bilious vomiting, and epigastric pain, possibly with excessive enterogastric reflux.⁸ There does not appear to

Figure 35-10 Afferent loop syndrome following Roux-en-Y gastrojejunostomy. **A, B.** Axial-contrast enhanced CT images **A.** A small gastric remnant (S) is anastomosed to a jejunal Roux limb (J). **B.** There is a small bowel anastomosis in the left midabdomen (white arrow). The afferent limb is markedly dilated and fluid-filled, with distention of the duodenum (D). The efferent jejunal limb is decompressed (black arrow). **C.** Overhead radiograph following UGI shows a dilated gastric remnant (S) with reflux into the esophagus. There is preferential filling of a dilated afferent limb (A) and duodenum (D). Note contrast in the right colon from a prior study.

be a strong correlation between the degree of inflammation and the degree of symptoms. The onset of pain is not associated with meals. The differential diagnosis may include afferent loop syndrome, obstruction, and gastric stasis, and UGI may help establish the diagnosis. UGI may reveal thickened gastric folds without associated obstruction (Fig. 35-11). Ulcers may or may not be present in the perianastomotic region of the gastric remnant.⁴

Conversion to Roux-en-Y gastrojejunostomy with at least 45 cm of isoperistaltic jejunal loop between the gastric remnant and duodenum may help alleviate bile reflux gastritis by diverting bile and pancreatic secretions away from the gastric remnant.^{8,32}

Neoplasms After Surgery for Benign Ulcer Disease

Following partial gastrectomy for benign disorders, especially PUD, there is an increased risk of gastric remnant neoplasms.^{30,46} This occurs in the late postoperative course, with a 15- to 20-year latent period, at which point the relative risk increases twofold to fourfold.⁴⁷ Malignant tumors most likely develop as a result of gradual progression from normal mucosa to intestinal metaplasia to dysplasia, and, subsequently, to cancer over time, presumably as a consequence of prolonged achlorhydria and chronic enterogastric reflux of bile and pancreatic secretions.⁴⁸ Truncal vagotomy reduces gastric acid and may contribute to this process. Stump tumors involve the distal gastric remnant at or near the anastomosis.⁴⁶ On UGI, stump tumors appear as infiltrating, plaquelike, polypoid, or ulcerative lesions in the gastric remnant near the anastomosis.

Figure 35-11 Bile reflux gastritis following Billroth II. A supine double-contrast UGI image shows distal gastrectomy with gastrojejunostomy. There are thickening and lobulated folds in the gastric remnant caused by bile reflux gastritis.

Surgical Considerations for Gastric and Duodenal Neoplasms

Gastric and duodenal neoplasms are discussed in detail elsewhere in this textbook. Neoplasms of the stomach and duodenum require resection, with the extent and location of resection dependent on the benign or malignant nature of the lesion, lesion location, extent of disease, and underlying physiologic status of the patient.

SURGERY FOR GASTRIC MASSES

The goal of surgical treatment for gastric tumor is to remove the grossly visible tumor completely and obtain histologically free surgical margins. The extent of the procedure depends on the degree of tumor infiltration in and through the gastric wall, extension into adjacent organs, and lymph node involvement. Upper endoscopy and endoscopic ultrasound (EUS) can be useful to determine the location and extent of disease spread within the gastric wall.⁹ It is essential to properly stage any patient who is being considered for subtotal gastrectomy for cancer prior to operative intervention. For example, when a total gastrectomy is planned, the proximal extent of disease should be determined preoperatively to determine whether a distal esophagectomy is also necessary.

There are several different surgical procedures that may be performed to treat gastric masses. The size and location of the tumor, in conjunction with the surgeon's experience and preference, help determine the exact surgical procedure performed. Malignant gastric lesions usually require distal or total gastrectomy.⁴⁹ Surgical procedures for gastric cancer may include a Billroth II, Roux-en-Y gastrojejunostomy, Roux-en-Y esophagojejunostomy, or primary esophagogastric anastomosis. Omentectomy and/or splenectomy may be performed simultaneously, if necessary.

The location of the primary tumor determines the type of resection performed.⁵⁰ For a lesion located in the mid to distal stomach, particularly along the greater curvature, subtotal gastric resection may be performed, ideally with margins of 5 to 6 cm around the lesion. A gastroenterostomy is performed to restore continuity of the GI tract. The need for wide margins usually requires a gastrojejunostomy rather than gastroduodenostomy, and a Billroth I is not typically performed for malignant disease. Gastrojejunostomy may be a loop-type or Roux-en-Y configuration.

Larger and more proximal tumors may require total gastrectomy with an esophagojejunal anastomosis, typically a Roux-en-Y esophagojejunostomy. The distal esophagus may also be resected with a more cephalad esophagojejunal anastomosis.⁹ For lesions in the proximal stomach, particularly within 5 cm of the gastroesophageal junction, proximal gastric resection may be possible with a primary esophagogastric anastomosis. However, proximal subtotal gastrectomy with esophagogastric anastomosis is not commonly performed because of problems with gastroesophageal reflux, and the anastomosis between the esophagus and distal stomach may be less secure, resulting in an increased risk of anastomotic leaks. Total gastrectomy with esophagojejunostomy may be preferable. However, anastomotic leaks are of particular concern following esophagojejunostomy, occurring in up to 12% of patients and with a mortality of approximately 33% (Fig. 35-12).⁵¹

Figure 35-12 Leak following total gastrectomy and esophagojejunostomy. A supine UGI image using water-soluble contrasts shows a Roux-en-Y esophagojejunostomy. There is a leak (arrows) from the anastomotic area with contrast opacifying a large collection (C) in the right upper abdomen. J, jejunum.

SURGERY FOR DUODENAL MASSES

Resection of duodenal malignancies typically requires pancreaticoduodenectomy. This entails reanastomosis of the GI tract, bile duct, and pancreatic remnant. Distal gastrectomy may be performed with a gastrojejunostomy. Alternatively, the stomach and pylorus may be preserved with an end-to-side proximal duodenojejunostomy just distal to the pylorus, also known as a pyloric-sparing Whipple procedure. The bile duct and residual pancreas may be anastomosed separately to the jejunum with a pancreaticojejunostomy and choledochojejunostomy.

COMPLICATIONS FOLLOWING GASTRIC AND DUODENAL SURGERY FOR NEOPLASM

In general, perioperative and postoperative morbidity is relatively common following surgery for gastric cancer. Resections may be extensive, and patients tend to be relatively debilitated. The complications of diarrhea, dumping syndrome, malnutrition, and weight loss increase postoperative difficulties. Following gastric resection and with denervation of the stomach, there may be alterations to intestinal motility, absorption, and biliary kinetics.

A variety of physiologic and metabolic problems may arise, and these problems may be increased with a larger gastric resection.³⁰ Chronic nutritional problems can be serious, outweighing other complications and concerns. Potential metabolic problems following gastrectomy include iron or vitamin B₁₂ deficiency, anemia, malnutrition, weight loss, and bone disease (e.g., osteomalacia, osteoporosis). Anemia may occur following

Figure 35-13 Recurrent tumor following distal gastrectomy for gastric cancer. **A.** Supine UGI image shows thickened, lobulated folds along the distal gastric remnant and gastrojejunal anastomosis (*black arrows*). There are also tumor implants (*white arrow*) along the jejunal limb (J). **B, C.** Axial contrast-enhanced CT scans show lobulated soft tissue along the distal gastric remnant (*white arrows*) caused by tumor recurrence. Also note a tumor implant (*black arrow*) along the jejunal limb (J).

gastric surgery because of malabsorption, inadequate oral intake, and/or chronic blood loss. If a partial pancreatic resection has been performed, there may also be a deficiency of digestive enzymes, resulting in malabsorption.

Gastric resection for neoplasm can result in many of the same complications as gastric resection for PUD, including leaks, obstruction, stomal ulcers, and other mechanical problems. In addition to the many benign causes of obstruction that are seen following surgery for PUD, obstruction following surgery for gastric or duodenal neoplasm can be caused by local tumor recurrence, metastatic nodal masses, or peritoneal carcinomatosis.⁴²

Recurrent Carcinoma

Patients who have undergone partial gastrectomy for gastric cancer are at continued risk of developing tumor recurrence. Recurrence in the surgical bed can be in the form of local bowel tumor recurrence, regional adenopathy, or tumor implants from carcinomatosis.

On UGI following partial gastrectomy for a localized gastric carcinoma, tumor recurrence may appear infiltrating, plaque-like, polypoid, and/or ulcerative. There may be narrowing and decreased distensibility of the gastric remnant, with straightened and irregular contours.⁴ Comparison with a baseline postoperative study may be helpful for differentiating recurrent tumor from postsurgical plication defects and suture-related changes. There may be mass effect on the bowel, with spiculated, tethered folds caused by tumor implants (*Fig. 35-13*).

CT may detect local tumor recurrence, regional adenopathy, and tumor implants. Recurrent tumor at the anastomosis may be manifested by focal irregular bowel wall thickening, often with soft tissue density in the bowel wall (see *Fig. 35-13*). CT can also readily identify distant nodal metastases and hematogenous metastases to solid organs and osseous structures.²⁶

Surgery for Weight Loss

Obesity is an epidemic in the United States and the Western world that has had an increasing impact on radiology. Obesity is typically defined in terms of body mass index (BMI), which provides a standard definition for national surveillance and takes into account patient weight and height. BMI is expressed as kg/m^2 . Overweight is defined as a BMI of greater than 25 kg/m^2 , obese as greater than 30 kg/m^2 , morbidly obese as greater than 40 kg/m^2 , and superobese as greater than 50 kg/m^2 .^{52,53} Weight concerns have been increasingly prevalent in the United States. There has been a 74% increase in obesity between 1991 and 2001 and, from 1960 to 2000, the prevalence of obesity has more than doubled and the prevalence of morbid obesity has quadrupled.⁵³⁻⁵⁵ Currently, more than 65% of U.S. adults are considered overweight or obese, with more than 30% of the population considered obese and 5% to 7% considered morbidly obese.^{53,56}

Bariatric surgery is a successful treatment option for morbid obesity with regard to long-term weight loss, decreased morbidity, and improved life expectancy.^{55,57,58} Bariatric procedures

have increased by more than 800% in the United States between 1998 and 2004, and more than 220,000 procedures are performed annually.^{54,59} Bariatric surgery is typically reserved for patients who fail to lose weight with conservative measures, including diet, exercise, and behavior modification. Surgical techniques for weight loss include malabsorptive, restrictive, or combination (restrictive and malabsorptive) procedures.

Malabsorptive procedures bypass a segment of small bowel to decrease the length of the absorptive surface. The classic malabsorptive procedure is the jejunioileal bypass.

Restrictive procedures combine a small gastric pouch with a narrow outlet to induce early and prolonged satiety. A small gastric pouch is created to limit food intake and create early satiety. This is combined with a narrow outlet or stoma to delay emptying and prolong satiety. Examples of restrictive procedures include laparoscopic adjustable gastric banding, horizontal and vertical gastropasty, and sleeve gastrectomy.

Combination procedures use both restrictive (small gastric pouch, narrow outlet) and malabsorptive (bypass of a small bowel segment) components. These include the Roux-en-Y gastric bypass and biliopancreatic diversion.

The original bariatric procedure was a malabsorptive procedure, known as the jejunioileal bypass. This was developed in the 1950s and involved joining the proximal small intestine to the distal small intestine, bypassing a large segment of small bowel. The stomach and duodenum were left intact. This procedure resulted in successful weight loss, but was associated with significant complications from malabsorption. Malabsorption can cause mineral and electrolyte imbalances, vitamin depletion, protein calorie malnutrition, anemia, and peripheral neuropathy. The jejunioileal bypass resulted in liver disease in up to 30% of patients, liver failure in up to 10% of patients, and renal failure in up to 37% of patients. This procedure is no longer performed because of the severity of complications.⁶⁰

Subsequently, restrictive bariatric procedures were developed. Restrictive procedures have been a popular treatment option for bariatric surgeons and include gastropasties, gastric band placements, and sleeve gastrectomies. Gastropasty is a purely restrictive procedure in which a small gastric pouch is created with a narrow stoma to communicate with the remainder of the stomach. The remainder of the GI tract is left intact. In a horizontal gastropasty, there is a staple line along the proximal stomach, with a central or greater curvature stoma. This procedure had limited long-term success because of gastric wall stretching, with pouch and stomal enlargement. There were also problems with frequent staple line disruptions. Following initial success, many patients stopped losing weight or actually gained weight.

The vertical banded gastropasty (VBG) creates a small gastric pouch along the proximal lesser curvature of the stomach, with a vertical staple line along the proximal stomach. The lesser curvature of the stomach is thicker and stretches less as compared with the greater curvature. A polypropylene band is placed around the stoma to prevent stretching. Circular staples create a window for the band, and identification of the circular staples on a radiograph indicates that a VBG was performed. VBG has resulted in adequate weight loss and remains popular outside the United States. However, VBG requires patient compliance and will fail with maladaptive eating. Complications include pouch dilation, stomal stenosis, staple line dehiscence, gastroesophageal reflux, and vomiting. In the

United States, the VBG has been replaced by other bariatric procedures.

Currently, the most common bariatric procedures performed in the United States are the Roux-en-Y gastric bypass, laparoscopic adjustable gastric banding, and the gastric sleeve procedure (sleeve gastrectomy). Certain challenges may arise when imaging bariatric patients because of body habitus, specifically with regard to patient weight and abdominal girth. Imaging equipment capacity may be a concern, and procedural modifications are often necessary for radiography, UGI, and CT studies in this setting.^{54,59}

ROUX-EN-Y GASTRIC BYPASS

The Roux-en-Y gastric bypass (RYGB) is a proven bariatric procedure with the highest long-term success rates and the most sustained weight loss compared with other bariatric procedures.^{55,57,58,61,62} RYGB has been the most common bariatric procedure performed in the United States in recent years.⁶³

RYGB is a combined procedure that is predominately restrictive, but also has a malabsorptive component. In this procedure, a small gastric pouch is created to exclude the remainder of the stomach and duodenum (biliopancreatic limb) from the path of food. A jejunal Roux limb is brought up to the gastric pouch in antecolic or retrocolic fashion (retrocolic through a defect in the transverse mesocolon). A narrow gastrojejunal anastomosis or stoma is created between the gastric pouch and Roux limb. The small gastric pouch and narrow stoma comprise the restrictive component of the procedure (Fig. 35-14A). The length of the bypassed small bowel can be varied to increase or decrease the amount of the malabsorptive component. The Roux limb typically has a short, oversewn or blind-ending component and an antegrade-flowing component or alimentary limb (because of an end-to-side anastomosis). The alimentary limb is anastomosed downstream to the biliopancreatic limb with a side-to-side jejunojejunal (JJ) anastomosis, usually in the left midabdomen. This procedure therefore creates an alimentary limb, biliopancreatic or excluded limb, and distal common channel downstream from the JJ anastomosis (see Fig. 35-14A).

Assessing Postoperative Complications

Despite the success of RYGB, many complications can occur. Knowledge of the expected postsurgical anatomy is essential to assess for postoperative complications following RYGB.

Upper Gastrointestinal Examination. Following RYGB, a UGI may be performed early postoperatively to assess for complications, including leak or obstruction. In the late postoperative course, patients may undergo evaluation because of epigastric pain, dysphagia, failed weight loss, excessive weight loss, or symptoms of obstruction. As with patients following gastric or duodenal surgery for PUD or neoplasm, in the early postoperative course, water-soluble contrast should be administered initially to assess for leakage. If no leak is seen with water-soluble contrast, barium may be administered. In the late postoperative course, barium may be administered initially.

Initial fluoroscopic evaluation should be performed with the patient in the left posterior oblique (LPO) position. This is the ideal position to assess the proximal postsurgical anatomy, including the gastrojejunal (GJ) anastomosis. Rapid sequence imaging may help acquire images with optimal distention of the

Figure 35-14 Roux-en-Y Gastric Bypass **A.** RYGB anatomy. A small gastric pouch (P) is created to exclude the remainder of the stomach and the duodenum from the path of food. There is a gastrojejunostomy with a jejunal Roux limb (J) anastomosed to the pouch via a narrow stoma and a more downstream jejunojejunostomy (arrow). This creates an alimentary limb (pouch, Roux limb), biliopancreatic limb (including the excluded stomach and duodenum), and downstream common channel. **B.** UGI image in the LPO position shows a small gastric pouch (P) with a narrow anastomosis (arrow) to the jejunal Roux limb (J). Note the surgical drain. **C.** Axial contrast-enhanced CT scan with oral and IV contrast shows an opacified small gastric pouch (P) anastomosed (arrow) to the jejunal Roux limb (J). There is a small amount of fluid in the excluded stomach (ES).

pouch, stoma, and adjacent Roux limb (Fig. 35-14B). Additional fluoroscopic views may be obtained as necessary. Overhead radiographs should be obtained serially until contrast passes the JJ anastomosis in the early postoperative course, because leak or obstruction may rarely occur at this site. In the late postoperative course, the study should be continued until the terminal ileum is opacified because complications of obstruction or internal hernia may not become apparent until the terminal ileum is opacified.

Computed Tomography. RYGB patients are ideally imaged following administration of positive oral contrast and IV contrast. Positive oral contrast administered just prior to the study should opacify the gastric pouch and alimentary limb. This should help distinguish the alimentary limb from the excluded biliopancreatic limb (Fig. 35-14C). Again, water-soluble contrast is administered in the early postoperative course or if perforation is a concern. On CT, the gastric pouch, GJ anastomosis, Roux limb, excluded stomach, biliopancreatic limb, and JJ anastomosis

should be visualized and evaluated. The JJ anastomosis is usually found in the left midabdomen.

Complications

Extraluminal Leak. The most common serious complication in the early postoperative course following RYGB is a postoperative leak, occurring in up to 6% of patients and usually diagnosed within 10 days of surgery.^{61,62,64} Postoperative leaks are associated with increased postoperative morbidity and mortality, and additional surgery may be required in up to 80% of patients.⁶⁴ To decrease morbidity following a leak, early diagnosis and treatment are essential.

On UGI following RYGB, leakage usually extends to the left of the GJ anastomosis into the left upper quadrant of the abdomen.^{64,65} The majority of leaks (more than 75%) arise from the GJ anastomosis. Leaks may also arise from the distal esophagus, gastric pouch, blind-ending jejunal limb and, rarely, the JJ anastomosis.⁶⁴ A UGI can demonstrate the origin and extent of leak with opacification of an extraluminal collection or tract,

Figure 35-15 Leak following RYGB. A supine UGI image shows an edematous gastric pouch (P) and jejunal limb (J). There is as large leak from the gastrojejunal anastomosis opacifying a large left upper quadrant collection (C) as well as the surgical drain (arrows).

usually in the left upper quadrant (Fig. 35-15). On occasion, the sole manifestation of leak may be contrast opacification of an indwelling surgical draining. This may be best identified on a postprocedural radiograph.

It is important to assess for leakage at the outset of the fluoroscopic study. Later on during the procedure, the excluded stomach may become opacified via retrograde flow. This can appear as a collection of contrast in the left upper quadrant of the abdomen. The intragastric location may be confirmed by rotating the patient to the right to opacify the more distal excluded stomach and duodenum.⁶⁵ An anastomotic leak must also be distinguished from a postsurgical plication defect on UGI. A plication defect is a focal outpouching along the suture line that will readily fill and empty with contrast material during the study and will have well-defined margins. A leak typically appears more ill-defined, with stasis of contrast.

Communication with the Excluded Stomach. During the RYGB procedure, the gastric pouch is separated from the remainder of the stomach by a staple line or by complete transection. Staple line dehiscence or disruption allows communication between the gastric pouch and remainder of the stomach. This may be caused by overdistention of the pouch with food or inadequate initial surgical division. In the case of complete transection, communication with the excluded stomach can occur via a gastrogastic fistula. Overall, communication between the pouch and excluded stomach occurs in up to 4% of patients, and this complication allows ingested material to enter the excluded stomach. As a result, there may be inadequate weight loss or actual weight gain, and elective surgical revision may be necessary for a more optimal clinical outcome.⁶⁶

In the acute postoperative course, leakage into the excluded stomach may be a consequence of a free leak. An early postoperative leak into the excluded stomach is associated with

Figure 35-16 Staple line dehiscence following RYGB. A right lateral UGI image shows opacification of the gastric pouch (P) and the jejunal limb (J) following RYGB. Contrast material is also seen crossing the gastric staple line (arrow) to opacify the excluded stomach (ES).

an extraluminal leak in as many as 88% of patients.⁶⁶ In the remote postoperative course, communication with the excluded stomach will usually result in failure of the procedure, with failure of weight loss or recurrent weight gain in up to 61% of patients.⁶⁶

On UGI, the gastric pouch will be opacified along with the excluded stomach, with contrast crossing the gastric staple line (Fig. 35-16) or entering the excluded stomach via a gastrogastic fistula. Depending on the significance of the communication, contrast may preferentially enter the excluded stomach or jejunal Roux limb. This diagnosis should be made at initial fluoroscopy, because later on during the study contrast may enter the excluded stomach via retrograde flow. In the early postoperative course, it also is important to assess for an associated free leak.

Communication between the gastric pouch and excluded stomach may be difficult to diagnose accurately on CT. It may not be possible to distinguish contrast material in the excluded stomach because of staple line dehiscence from retrograde flow. The presence of contrast material in the excluded stomach but not in the duodenum on CT may suggest communication with the excluded stomach; however, UGI may be necessary for a more definitive diagnosis.⁶⁶

Marginal Ulcers. Marginal ulcers following RYGB occur near the GJ anastomosis in up to 3% of patients because of exposure of the jejunal mucosa to gastric secretions.⁶⁷ On UGI, a marginal ulcer appears as a focal outpouching near the GJ anastomosis, with stasis of contrast material in the crater and associated fold thickening and edema. Marginal ulcers decrease in

incidence with smaller pouch size and tend to respond well to medical management. Occasionally however, surgical treatment may be required.

Obstruction

Acute Obstruction. Obstruction in the early postoperative course is most often caused by postoperative edema and/or hematoma, typically involving the GJ or JJ anastomosis. In addition, in the setting of a retrocolic Roux limb, edema or a hematoma may occur where the Roux limb crosses the transverse mesocolon. Narrowing in any of these locations can cause obstruction.

Acute obstruction caused by edema or a hematoma usually resolves spontaneously with delayed initiation of diet. However, significant narrowing of the JJ anastomosis may require surgical intervention. Edema at the JJ anastomosis can result in acute distention of the excluded stomach. This can exert pressure on the gastric staple line and result in perforation if not promptly treated. Acute gastric distention may be temporarily relieved by percutaneous gastrostomy catheter placement until the edema resolves.

Late Obstruction. Small bowel obstruction following RYGB occurs in approximately 5% of patients, with a similar incidence following open and laparoscopic technique.^{68,69} Obstruction in the late postoperative course may be caused by adhesive disease, internal hernias, stomal stenosis, abdominal wall hernias, and, rarely, intussusception.⁶⁸ Following open surgery, adhesions are the usual cause of obstruction. Alternatively, after laparoscopic RYGB, internal hernias are a more common cause. Presumably, a lack of adhesions following laparoscopic surgery allows for increased bowel mobility and an increased potential for internal hernias.^{68,70,71}

Patterns of Small Bowel Obstruction. Because of the alterations made to the GI tract following RYGB, there are three patterns of obstruction that can occur relative to the JJ anastomosis. The pattern of obstruction can be classified according to an ABC taxonomic system.^{65,72}

Type A obstruction occurs with dilation of the alimentary limb only. The biliopancreatic limb is decompressed. This should be readily diagnosed on UGI with a dilated Roux limb extending toward the JJ anastomosis (Fig. 35-17). On CT, the diagnosis may be difficult because the excluded stomach and duodenum will be decompressed, and identification of the RYGB anatomy and dilated Roux limb are necessary to make the diagnosis.

In type B obstruction, there is dilation of the biliopancreatic, or excluded, limb only. On UGI, diagnosis may be difficult because the biliopancreatic limb is not routinely opacified. It may be possible to infer the diagnosis from displacement of the Roux limb by a fluid-filled, dilated biliopancreatic limb. On CT, the excluded stomach and duodenum will be dilated and fluid-filled, but it is essential to recognize the RYGB anatomy and identify a decompressed Roux limb to make this diagnosis. This represents a type of closed loop obstruction, with no natural means to decompress the excluded stomach. Percutaneous gastric decompression may therefore be necessary to alleviate the pressure and prevent perforation and additional complications.

In type C obstruction, there is obstruction at the level of the common channel, with dilated alimentary and biliopancreatic limbs (via retrograde flow; Fig. 35-18).

Figure 35-17 Obstruction of the alimentary limb following RYGB caused by JJ stomal stenosis. An overhead radiograph from UGI shows a dilated gastric pouch (P) and jejunal Roux limb (J) (alimentary limb) extending toward an abrupt transition at the JJ anastomosis (arrow) caused by stomal stenosis and fibrosis.

Internal Hernia. Internal hernia (IH) occurs in approximately 3% of RYGB patients and is more common following laparoscopic than open surgery.^{61,67,73} This is considered a late postoperative complication; however, IH can occur at any time following RYGB and can occur on multiple occasions.

With an IH, bowel herniates through a mesenteric defect, usually a surgically created defect. The most common defects following RYGB include a defect in the transverse mesocolon for a retrocolic Roux limb, mesenteric defect for the JJ anastomosis, and defect posterior to the Roux limb (Petersen's defect).^{67,71,73,74} IH can result in obstruction, ischemia, infarction, and bowel perforation and can be a life-threatening complication of RYGB, especially if diagnosis and treatment are delayed. However, the diagnosis of IH can be problematic clinically and with imaging studies. Symptoms may be nonspecific or intermittent, and a high index of suspicion is necessary. On UGI and CT, knowledge of the postoperative anatomy and changes to the expected course of the bowel are essential to make the diagnosis.⁷³

UGI findings of IH may include an abnormal bowel configuration with clustered, displaced small bowel loops. Clustered small bowel is usually found in the left abdomen (90%), but clustered small bowel can be located anywhere in the abdomen and pelvis (Fig. 35-19). Clustered bowel may be seen displacing other bowel. A small bowel limb may be seen entering and exiting the clustered segment, and stasis of contrast tends to

Figure 35-18 Small bowel obstruction following RYGB with obstruction of the common channel. A, B. Axial CT images following positive oral and IV contrast show marked dilation of the excluded stomach (ES) and duodenum (D) as well as the opacified Roux limb (R) caused by downstream obstruction of the common channel. Also note that oral contrast is present in the excluded stomach but not the duodenum because of staple line dehiscence more cephalad (not shown).

Figure 35-19 Internal hernia following RYGB. An overhead radiograph during UGI with small bowel follow-through on an RYGB patient shows an atypical bowel configuration, with clustered, displaced small bowel loops in the right midabdomen. A small bowel limb can be seen entering and exiting the clustered segment (arrows).

occur in clustered bowel.⁷³ A change in bowel configuration as compared with a prior study may be seen with displacement of a JJ suture line, usually into the left upper quadrant.⁷³

CT in the setting of internal hernia will also show clustered small bowel in an atypical location (Fig. 35-20). Associated mesenteric findings can be identified, including swirling and stretching of the mesenteric vessels. Findings of IH on CT include small bowel in the left upper quadrant above the transverse mesocolon, cephalad displacement of the JJ anastomosis,

clustered blood vessels in the left upper quadrant, and a swirling appearance of mesenteric fat or vessels.^{75,76} Comparison with a prior postoperative study is helpful to identify a change in the bowel configuration.

Stomal Stenosis. Stomal stenosis may occur at the GJ or JJ anastomosis, typically in the late postoperative course. GJ stomal stenosis occurs in up to 10% of patients, results in a dilated gastric pouch and esophagus with delayed emptying, and tends to respond well to endoscopic dilation. JJ stomal stenosis is less common, occurring in less than 1% of patients, but is less often successfully treated with endoscopic dilation and may require surgical revision (see Fig. 35-17).^{65,77}

Abdominal Wall Hernias. Abdominal wall hernias are much less common following laparoscopic RYGB as compared with open technique, but can occur at any incision or port site and can cause obstruction. Obstruction is more commonly caused by hernias with a small neck as compared with larger hernias.^{61,65}

Intussusception. Intussusception following RYGB is usually associated with the JJ anastomosis. The suture line may in some way act as a lead point. Also, there is altered motility in the vicinity of the anastomosis. Intussusception is often transient, but may be a fixed finding, rarely resulting in obstruction and incarceration (Fig. 35-21).^{65,78}

LAPAROSCOPIC ADJUSTABLE GASTRIC BANDING

Gastric band placement is a restrictive procedure that limits the volume of food that can be consumed. The first gastric band was introduced in 1986 and was made available laparoscopically in the early 1990s. The first *adjustable* gastric band device was approved for use in the United States by the U.S. Food and Drug Administration (FDA) in 2001. Since then, additional versions of the band have been approved, and the concept of a reversible, adjustable gastric band has become an increasingly popular treatment option for morbid obesity in the United States.⁷⁹

Laparoscopic adjustable gastric band placement (LAGB) is the least invasive bariatric procedure to date; it involves no cutting, stapling, or bypassing of portions of the GI tract. The

Figure 35-20 Internal hernia following RYGB on CT. A, B. Axial CT images following positive oral and IV contrast show RYGB anatomy with the Roux limb (R) clustered, dilated, and displaced cephalad to the pouch (P) and compressing the excluded stomach (S) secondary to an internal hernia. The JJ suture line was also displaced cephalad (not shown).

Figure 35-21 Intussusception following RYGB on CT. Axial CT scan following positive oral and IV contrast shows a fixed intussusception about the JJ anastomosis, with focal bowel dilation and dilation of the fluid-filled duodenum (D) caused by associated obstruction of the biliopancreatic limb (type B obstruction). Note anastomotic suture (arrows).

procedure is reversible, and the band can be adjusted according to the patient's weight loss curve and/or symptoms. Weight loss results with LAGB are similar to those of other restrictive procedures, but overall weight reduction may be less than RYGB in the long term, particularly in superobese patients (BMI > 50 kg/m²).⁸⁰⁻⁸³ Nevertheless, LAGB is an effective weight loss procedure, with improved obesity-related comorbidities, and has less overall morbidity as compared with RYGB.^{80,81,83}

The LAGB procedure consists of placing a silicone band around the upper stomach to create a small gastric pouch and a narrow stoma through the band that communicates with the remainder of the stomach (Fig. 35-22A).^{79,80} The small pouch and narrow stoma limit food intake and delay emptying. The band is sutured to the adjacent stomach wall to help hold it in place and decrease the chance of band slippage. The band has an inflatable inner balloon cuff connected via tubing to a subcutaneous port in the anterior abdominal wall, usually along

the right anterior rectus sheath. The port may be accessed percutaneously to inflate or deflate the balloon cuff of the band and adjust the size of the stoma. The stomal diameter may be narrowed by injecting the port with fluid to inflate the cuff or widened by aspirating fluid from the port to deflate the cuff. Inflation of the band can be performed in small increments to avoid complications from obstruction. Also, fluid can be removed from the band if the patient is experiencing obstructive symptoms.

Imaging Following Laparoscopic Adjustable Gastric Banding

Radiography. The radiopaque band should be located in the left epigastric region (Fig. 35-22B). The angle of the long axis of the band with the vertical (along the patient's spine) should be 4 to 58 degrees in the anteroposterior projection. This is called the phi angle. The device, connecting tubing, and port should be assessed to ensure that the device is intact, without kinking or discontinuity.

Upper Gastrointestinal Examination. Early postoperative UGI is useful to evaluate band position and assess for possible leakage or obstruction. On a scout radiograph, the location and angle of the band should be assessed, as well as the continuity of the connecting tubing and position of the reservoir. Before administering oral contrast, the patient should be positioned at fluoroscopy so the band is visualized in profile, usually with the patient in the supine anteroposterior or slight right posterior oblique position. In this position, the ring should appear as a straight line rather than having an O shape configuration (Fig. 35-22C). This allows for optimal evaluation of the pouch and stoma through the band and helps ensure that opacification of the fundus does not obscure the stoma. During the early postoperative course, water-soluble contrast should be administered followed by barium if no leak is detected. In the late postoperative course, and if there is no concern for perforation, barium may be administered initially.

As for all patients following gastric surgery, initial attention should be directed toward the postoperative anatomy, in this case, the gastric pouch and stoma. Ingested contrast should be followed fluoroscopically from the esophagus into the pouch, through the stoma created by the band, and into the remainder

of the stomach (see Fig. 35-22C). The distal esophagus, pouch size and configuration, and stomal diameter should be evaluated. The ideal stoma size has been reported to be 3 to 5 mm.⁸⁴ Fluoroscopy also allows for assessment of esophageal motility, esophageal and pouch dilation, and changes over time during the study.

Computed Tomography. Following LAGB, CT may be helpful to assess for a source of infection and evaluate soft tissue changes related to the device components. CT studies should include the abdominal wall soft tissues in the field of view because soft tissue processes related to the tubing or port might otherwise be missed. The radiopaque band should be identified along the proximal stomach (Fig. 35-22D); the tubing can be followed along its intraperitoneal course and in the overlying soft tissues as it connects to the port in the abdominal wall.

Band Adjustment

Periodic band adjustments following LAGB are typically necessary to achieve optimal weight loss and minimize symptoms of obstruction. Band adjustments may be performed at fluoroscopy. Ideally, the patient is administered oral contrast before and after adjustment to evaluate for adequate change in stomal caliber and prevent obstruction caused by an overinflated band. The use of fluoroscopy allows for an accurate adjustment of stomal size and also decreases potential complications from an excessively narrowed stoma, including obstruction, motility disorders, pouch dilation, band slippage, and band migration. Several band adjustments may be necessary to achieve an optimal result in terms of weight reduction, with an average of three adjustments necessary per patient.⁸⁵⁻⁸⁷

The degree of adjustment is best determined in conjunction with the surgeon and is based on the patient's weight loss curve and symptomatology. At fluoroscopy, the subcutaneous port is localized, and a noncoring, deflected-tip, 20- to 22-gauge needle with an attached, saline-filled syringe is inserted and advanced until it hits the back wall of the reservoir. Saline should be easily injected and withdrawn to confirm appropriate position. The amount of saline instilled or removed should be documented. After adjustment, oral contrast is administered to confirm adequate narrowing of the stoma without obstruction.

Complications

Overall, LAGB is a relatively safe surgical procedure, with minimal perioperative mortality, but some degree of morbidity occurs in up to 35% of patients and additional surgery may be necessary in as many as 11% of patients.^{80,81,88} Additional surgical procedures are often performed laparoscopically and may be relatively minor in nature (such as involving the port or tubing).

Following LAGB, early complications are rare and may include gastric perforation in less than 0.5% of patients, improper band positioning in less than 0.1% of patients, early postoperative band slippage in less than 0.1% of patients, and acute stomal obstruction in less than 1.4% of patients.^{80,81,83-85,88} Early dysphagia and pouch esophageal reflux are common until dietary habits change.

Complications following LAGB are much more common in the late postoperative course; these may include pouch dilation, band slippage, band erosion, obstruction, and device-related complications, including device failure. The most common late complications are pouch dilation and band

slippage, and early diagnosis is important to prevent further complications.^{85,86,88} Gastric necrosis is rare, occurring in less than 0.3% of patients, and is most often caused by band slippage with strangulation.^{80,81,83}

Pouch Dilation. Pouch dilation may occur in as many as 25% of patients following LAGB, but the incidence has decreased over time with surgical modifications of the gastric band procedure.⁸⁹ As in all bariatric procedures, dilation of the pouch can result in failed weight loss. Also, pouch dilation may necessitate removal of the device.

Upper Gastrointestinal Examination. Pouch dilation following LAGB can be seen with a normal or widened stoma, narrow stoma, or band slippage. In the case of a normal or widened stoma, pouch dilation is usually caused by dietary noncompliance and chronic overfilling of the pouch. The pouch is dilated and has a concentric appearance, and the stoma is widely patent (Fig. 35-23). This may require nutritional counseling.^{79,84,90} In the case of pouch dilation with a narrow stoma, pouch configuration should be evaluated (concentric or eccentric dilation). Concentric pouch dilation with a narrow stoma may occur in the acute setting, with vomiting, dysphagia, esophageal dysmotility, and obstruction (Fig. 35-24). This is usually caused by band overinflation at adjustment. Rarely, focal weakness in the balloon cuff can result in eccentric stomal narrowing, with concentric pouch dilation. When pouch dilation caused by a tight stoma is identified, the band should be deflated immediately to prevent further complications.^{79,85} Eccentric pouch dilation with a tight stoma is caused by band slippage (Fig. 35-25; see later).

Computed Tomography. Pouch dilation may be recognized on CT, especially with coronal and sagittal images, but the caliber of the stoma is not well assessed on CT. If pouch dilation is noted on CT, UGI may be of benefit to determine if there is obstruction caused by the band.

Pouch Dilation with Band Slippage. Pouch dilation may be a consequence of band slippage. In this case, the band becomes

Figure 35-23 Concentric pouch dilation following LAGB with a widened stoma. Supine UGI image obtained during drinking shows a concentrically dilated pouch (P) with a widened stoma (arrows) through the band. This is typically caused by chronic overdistention and may require nutritional counseling.

dislodged from its original position, with herniation of a portion of the stomach above the band. This results in an eccentrically dilated pouch, with a tight stoma. Band slippage may occur in as many as 24% of patients, but the incidence varies with the surgical technique used.^{80,84,89-91} Surgical procedural modifications and patient training in regard to modification of

eating habits have resulted in a decreased incidence of band slippage over time.⁸⁹ Risk factors for band slippage include overeating with overdistention of the pouch, band overinflation, and excessive vomiting.

Band slippage is considered a late complication of LAGB. Patients may present with acute food intolerance, pain, vomiting, progressive gastroesophageal reflux, esophageal motility disorders, early satiety, and aspiration pneumonia. Rarely, band slippage may result in sudden complete dysphagia, severe abdominal pain, and acute gastric obstruction. Three types of band slippage have been described—anterior, posterior, and concentric slippage, with complete displacement of the band distally. In all types of band slippage, similar consequences are possible. Progressive eccentric pouch dilation with progressive herniation of the stomach above the band may occur if untreated. Band slippage can lead to acute obstruction, gastric volvulus, ischemia, infarction, perforation, and hemorrhage. The most serious complication is necrosis of the gastric pouch. Early detection and treatment of band slippage are essential to prevent further complications. Once diagnosed, the band should be deflated immediately.⁹²

Radiography. On abdominal radiography, there is increased separation between the gastric band and medial aspect of the left hemidiaphragm. As the stomach herniates superiorly through a slipped gastric band, the band may tilt along its horizontal axis so that the anterior and posterior sides of the band are no longer superimposed. This can produce an O shape configuration, termed the *O sign*.⁹³ A more vertical or horizontal configuration of the band will result in an abnormal phi angle. An air-fluid level may also be seen within a dilated gastric pouch above the band (see Fig. 35-25A).

Upper Gastrointestinal Examination. On a preliminary radiograph, an abnormal band position is noted, with a change in configuration of the band as compared with a prior

Figure 35-24 Concentric pouch dilation following LAGB with a narrow stoma. Upright UGI image obtained during drinking shows a concentrically dilated pouch (P) with a tight stoma (arrow) through the band. The band is causing obstruction, and the upright position is necessary to empty the pouch. In this case, the band should be deflated to prevent further complications.

Figure 35-25 Band slippage following LAGB. **A.** Supine radiograph in the same patient as in Figure 35-22 1 year later shows a change in the configuration of the band (white arrow) (see Fig. 35-22B). It is now inferiorly located and horizontal in configuration. There is a dilated, gas-filled stomach bubble superior to the band (arrowhead). The port (black arrow) is relatively unchanged. **B.** UGI image shows an eccentrically dilated gastric pouch (P) above the horizontal band (arrow), with obstruction at the level of the band caused by band slippage. The esophagus is also dilated.

postoperative study. The band may be displaced inferiorly in a more vertical or horizontal configuration with an abnormal phi angle (see Fig. 35-25A). Following ingestion of contrast, eccentric pouch dilation is seen with a tight stoma at the level of the band (see Fig. 35-25B). Band slippage results in luminal obstruction by the band, and slippage may become more apparent with increased luminal distention during the study. Posterior slippage is associated with upward herniation of the posterior gastric wall through the band, and anterior slippage is associated with downward displacement of the band over the anterior wall of the stomach.^{79,85}

Intragastric Erosion and Migration of the Band. The gastric band can erode into the lumen of the stomach in approximately 2% of patients following LAGB, with a higher incidence reported with longer follow-up. With this complication, the band gradually erodes into the gastric wall, enters the lumen, and may even migrate distally, resulting in downstream obstruction. Band erosion may be a consequence of NSAID use, excessive vomiting, or increased pressure within the band itself from overinflation. Patients may present with nonspecific pain, GI bleeding, abdominal and/or port abscess, peritonitis, perforation, and, rarely, pneumoperitoneum. Patients with band erosion may also present with weight gain, despite seemingly adequate band adjustments, because the band is no longer creating a narrow stoma. Band migration requires removal of the band and repair of the stomach because this could lead to fatal hemorrhage.⁹⁴

On UGI, contrast material is seen surrounding the intragastric portion of the band, so that the band appears as an intraluminal filling defect within the stomach (Fig. 35-26). Contrast may or may not be seen within the stoma, depending on the

degree of erosion. Band erosion may be suspected on CT when contrast is seen within and surrounding the band or if the band is completely intraluminal. There may be associated inflammatory change, abscess formation, or peritonitis.

Device-Related Complications. Following LAGB, there may be problems related to indwelling foreign bodies, including the band, connecting tubing, and reservoir. Device-related complications have been reported in up to 26% of patients, and these complications tend to require surgical repair.^{88,95}

Infection of the port, connecting tubing, or band occurs in as many as 6% of patients. The abdominal wall port may migrate through the soft tissues or become inverted in as many as 3% of patients, precluding band adjustments. Leakage of contents from the band system results in spontaneous band deflation, occurring in up to 5% of patients. Fluid loss can occur from a defect in the port, tubing, or inflatable balloon cuff, and leakage from the system can result from the use of an inappropriate needle for port access. Acute band deflation widens the stoma, so these patients experience a sudden change in dietary habits and poor weight loss, despite seemingly appropriate band adjustments. If leakage from the system is suspected, a radiograph should be obtained to look for discontinuity or kinking of the connecting tubing or device. In addition, inserting a designated volume of saline into the port and measuring for a discrepancy on return may be helpful. Injection of the port with water-soluble contrast at fluoroscopy can diagnose a leak from the system and can determine the origin of the leak to help direct surgical intervention.^{85,86,88}

SLEEVE GASTRECTOMY

The laparoscopic sleeve gastrectomy (or gastric sleeve) was first introduced in 1999; it is a restrictive procedure that limits the volume of food that can be consumed. Initially, sleeve gastrectomy was performed as the first part of a planned, staged bariatric procedure for treatment of very high-risk or superobese (BMI > 50 kg/m²) patients to decrease perioperative morbidity and mortality. The first stage consisted of the sleeve gastrectomy. Following initial weight loss and clinical improvement, a second operation was performed at a later date. The second procedure could be a biliopancreatic diversion or Roux-en-Y gastric bypass. However, the success of the sleeve gastrectomy alone in some patients eliminated the necessity of the second operation, so sleeve gastrectomy is now increasingly used as a stand-alone procedure.⁹⁶ This procedure constituted approximately 5% of all bariatric surgeries in 2008.⁹⁷

The sleeve gastrectomy consists of resection of 70% to 85% of the stomach along the greater curvature. The remaining stomach has a tubular configuration, and the pylorus and duodenum are left intact (Fig. 35-27A). This restricts the gastric capacity while maintaining the normal pathway of food. Also, the tubular stomach, in conjunction with an intact pylorus, creates a high-pressure restrictive system. Unlike restrictive gastric banding, there is no need for periodic band adjustments or intervention, and there is no indwelling foreign body. Absence of an indwelling foreign body reduces the risk of infection, and there are no problems with slippage, erosion, or device malfunction. As compared with RYGB, there is no major alteration made to the course of the GI tract, and there is no risk of

Figure 35-26 Band erosion following LAGB. UGI image following LAGB obtained with the patient drinking shows a small gastric pouch (P). The band is in an appropriate linear position (black arrow) for UGI. Rather than opacifying a stoma through the band, contrast is seen surrounding the left aspect of the band so that this portion of the band appears as a filling defect (white arrow). This is caused by intragastric erosion of the band. The expected location of the stoma is denoted with an arrowhead.

Figure 35-27 Sleeve gastrectomy. **A.** Gastric sleeve, with approximately 70% of the stomach resected (*shaded area*) along the greater curvature and with relative sparing of the antrum. The pylorus and duodenum are left intact. **B.** Supine UGI image shows the narrowed, tubular configuration of the gastric sleeve (S) in a recently postoperative patient with an intact pylorus and duodenum (D). **C.** Axial contrast-enhanced CT scan shows a narrowed stomach, with sutures along the resected greater curvature (*arrows*) and prominence of mesenteric fat in the expected location of the remainder of the stomach. Also note evidence of surgical injury to the left lobe of the liver.

malabsorption. However, the sleeve gastrectomy procedure is not reversible.⁹⁸

Imaging Following Sleeve Gastrectomy

Upper Gastrointestinal Examination. As for all early postoperative patients, water-soluble contrast is first used to assess for possible leakage. Barium is administered if there is no leak identified or initially in the late postoperative course. Administration of oral contrast reveals a long narrowed, tubular gastric pouch. Narrowing of the stomach is seen along the greater curvature. The distal gastric antrum and pylorus are preserved (Fig. 35-27B). Gastric peristalsis may be significantly diminished or absent.⁹⁸

Computed Tomography. CT may be of benefit following sleeve gastrectomy to assess the postoperative anatomy and evaluate the surrounding structures. The gastric sleeve appears as a narrowed, tubular stomach, often with a staple line along the greater curvature. Prominence of the mesenteric fat may be seen in the expected location of the resected portion of the stomach (Fig. 35-27C). With a stand-alone sleeve gastrectomy,

no additional bowel suture line or anastomosis is seen, and no Roux limb should be seen extending toward the stomach. The duodenum and small bowel should have a normal course. However, a jejunal limb may be seen anastomosed to the gastric sleeve when sleeve gastrectomy is performed in conjunction with RYGB.

Complications

The overall complication rate following sleeve gastrectomy is approximately 5%. Potential complications include leakage, strictures, hemorrhage, and infection.⁹⁸

Postoperative leaks have been reported following sleeve gastrectomy in as many as 5% of patients. Leaks usually arise from the proximal end of the greater curvature staple line near the gastroesophageal junction and extend laterally (Fig. 35-28). Proximal gastric leaks may be difficult to treat, with prolonged associated morbidity.⁹⁹

Late complications include stricture, pouch dilation, gastric outlet obstruction, hiatal hernia, and gastroesophageal reflux. Postoperative strictures and fibrosis can occur at the upper, mid, or distal end of the staple line (Fig. 35-29). Strictures

Figure 35-28 Leak following sleeve gastrectomy. **A.** UGI image following sleeve gastrectomy shows contrast opacifying an edematous, narrowed, and irregular gastric sleeve (S), with leakage from the proximal sleeve (arrow) into an extraluminal collection (C) extending to the left. Additional amorphous extraluminal contrast is seen more inferiorly. **B.** Axial CT scan with IV and positive oral contrast shows the leak (arrows) from the gastric sleeve (S) with extraluminal contrast and gas laterally in the left upper quadrant.

Figure 35-29 Gastric sleeve with stricture and proximal pouch dilation. Supine UGI image in a patient following sleeve gastrectomy shows a focal stricture in the midsleeve (arrow) with proximal dilation of the sleeve (S).

may also involve the gastric pouch diffusely. Gastric dilation can occur because of underlying fibrosis and strictures or because of overdistention and stretching of the remaining stomach. As in all bariatric procedures, pouch dilation can result in failure to lose weight or weight gain. Focal strictures may respond to endoscopic dilation, but longer segments of narrowing may necessitate surgical revision or resection of portions of the pouch with a subsequent gastrojejunostomy. Postoperative gastroesophageal reflux is not uncommon, having been reported in as many as 21% of patients. Hiatal hernias and severe gastroesophageal reflux may necessitate conversion to RYGB.⁹⁸

BILIOPANCREATIC DIVERSION WITH DUODENAL SWITCH

Biliopancreatic diversion with duodenal switch (BPD-DS) includes restrictive and malabsorptive mechanisms of weight loss. A sleeve gastrectomy is performed to limit the size of the stomach (restrictive). The duodenum is transected at the level of the duodenal bulb, and the proximal ileum is brought up and anastomosed to the duodenal bulb. The pylorus remains intact. This creates an alimentary limb consisting of the gastric sleeve, pylorus, duodenal bulb, and proximal ileum (Fig. 35-30). The biliopancreatic limb consists of the more downstream duodenum and jejunum and is anastomosed to the distal ileum approximately 75 to 100 cm proximal to the ileocecal valve. The malabsorptive component is created by rearranging the small intestine to bypass the small bowel and separate the flow of food from bile and pancreatic juices, limiting the absorption of calories and resulting in weight loss.¹⁰⁰

BPD-DS is effective in terms of weight loss, and less patient compliance is necessary as compared with restrictive procedures alone. However, because of complications, including those from malabsorption, this procedure tends to be reserved for superobese patients. It remains less widely performed overall as compared with RYGB. There is an increased risk of nutritional deficiencies, osteoporosis, protein loss and malnutrition, anemia, chronic diarrhea, and dumping syndrome. Also, the risks and surgical complications are increased with multiple

Figure 35-30 Biliopancreatic diversion with duodenal switch. Overhead radiograph during UGI with small bowel follow-through shows a gastric sleeve (S) as the restrictive component of the procedure. There is an intact duodenal bulb (D) with a duodenal to proximal ileal anastomosis (arrow). This bypasses a long segment of small bowel and separates the biliopancreatic contents from the ingested material, resulting in malabsorption. There is a nasogastric tube in place.

anastomotic suture lines. Mechanical complications following BPD-DS occur in approximately 20% of patients and may include obstruction, abdominal wall hernia, and anastomotic leaks. Bowel obstruction is identified in as many as 16% of patients.¹⁰¹

TABLE
36-1

Gastric Ulcers (No Mass)

Cause	Location	Comments
EROSIONS		
Idiopathic	Antrum or body; often aligned on rugal folds	Varioliform erosions
Aspirin or other nonsteroidal anti-inflammatory drugs	Antrum or body; may be on or near greater curvature	Varioliform, linear, or serpiginous erosions
Crohn's disease	Antrum or body	Associated Crohn's disease in small bowel or colon
ULCERS		
<i>Helicobacter pylori</i>	Usually on lesser curvature or posterior wall of antrum or body	Accounts for 70%-80% of gastric ulcers
Aspirin or other nonsteroidal anti-inflammatory drugs	Distal half of greater curvature	May simulate malignant ulcer
Gastritis	Variable	Hypertrophic gastritis, granulomatous conditions, radiation, caustic ingestion, infections
Zollinger-Ellison syndrome	Variable	Associated ulcers in atypical locations; hypergastrinemia
Early gastric cancer	Variable	Nodular or deformed folds surrounding ulcer

TABLE 36-2
Gastric Mass Lesions

Cause	Radiographic Findings	Comments
BENIGN MUCOSAL LESIONS		
Hyperplastic polyps	Round sessile polyps in fundus or body; usually multiple	Not premalignant
Adenomatous polyps	Lobulated or pedunculated polyps in antrum; often solitary	Premalignant
Polyposis syndromes	Multiple polyps in stomach (also in small bowel or colon)	Familial adenomatosis polyposis, Peutz-Jeghers syndrome, Cronkhite-Canada syndrome, juvenile polyposis, Cowden's disease
Villous tumor	Giant mass with soap bubble appearance	Premalignant; rare in stomach
Bezoar	Giant masslike filling defect; freely movable	Unusual eating habits; gastroparesis or gastric outlet obstruction
MALIGNANT MUCOSAL LESIONS		
Carcinoma	Polypoid mass; ulceration common	Usually advanced gastric cancer but may occasionally be early cancer
BENIGN SUBMUCOSAL LESIONS		
Benign gastrointestinal stromal tumor	Smooth submucosal mass; ulceration common; rarely multiple	May be difficult to differentiate from malignant gastrointestinal stromal tumor
Leiomyoblastoma	Smooth submucosal mass; ulceration common	Risk of malignancy
Lipoma	Submucosal mass with changeable shape at fluoroscopy; fat density on CT	Usually asymptomatic
Hemangioma	Submucosal mass with phleboliths	Risk of massive gastrointestinal bleeding
Lymphangioma	Submucosal mass	Rare
Glomus tumor	Submucosal mass	Usually asymptomatic
Neurofibroma	Solitary or multiple submucosal masses	Von Recklinghausen's disease
Granular cell tumor	Solitary or multiple submucosal masses	Associated lesions on skin or tongue
Inflammatory fibroid polyp	Sessile or pedunculated polyp in antrum; usually solitary	Usually asymptomatic
Ectopic pancreatic rest	Submucosal mass with central umbilication; usually on greater curvature of distal antrum	Usually asymptomatic
Duplication cyst	Submucosal mass on greater curvature of antrum or body; rarely communicates with lumen	Usually asymptomatic during first year of life
Varices	Multiple submucosal masses in fundus (likened to a bunch of grapes)	Portal hypertension or splenic vein obstruction
MALIGNANT SUBMUCOSAL LESIONS		
Malignant gastrointestinal stromal tumor	Solitary, lobulated submucosal mass; ulceration or cavitation common	Better prognosis than carcinoma
Metastases	One or more submucosal masses; ulceration or cavitation common; bull's-eye lesions of varying sizes	Most commonly malignant melanoma or metastatic breast cancer
Lymphoma	One or more submucosal masses; ulceration or cavitation common; bull's-eye lesions of varying sizes	Usually non-Hodgkin's lymphoma
Kaposi's sarcoma	Multiple submucosal masses or bull's-eye lesions	Homosexuals with AIDS; usually have Kaposi's sarcoma on skin
Carcinoid	Multiple submucosal masses or bull's-eye lesions	Carcinoid syndrome uncommon
Leukemia	Multiple submucosal masses or polyps	Rare
Multiple myeloma	Multiple submucosal masses	Rare

TABLE
36-3

Thickened Gastric Folds

Cause	Distribution	Comments
BENIGN CONDITIONS		
Antral gastritis	Antrum	Epigastric pain or dyspepsia
<i>Helicobacter pylori</i> gastritis	Usually antrum or antrum and body; sometimes diffuse	Associated with peptic ulcer disease
Hypertrophic gastritis	Fundus and body	Increased acid secretion; frequent duodenal ulcers
Ménétrier's disease	Fundus and body (massive folds)	Hypochlorhydria and hypoproteinemia
Zollinger-Ellison syndrome	Fundus and body (increased secretions; ulcers common)	Hypergastrinemia resulting from non-beta islet cell tumors
Varices	Fundus and cardia (serpentine folds)	Portal hypertension or splenic vein obstruction
Eosinophilic gastritis	Antrum	Peripheral eosinophilia; history of allergic diseases
Crohn's disease	Antrum and body	Associated Crohn's disease in small bowel or colon
Sarcoidosis	Antrum	Pulmonary sarcoidosis
Tuberculosis	Antrum	History of AIDS or travel to endemic areas
Caustic ingestion	Antrum	History of caustic ingestion
Radiation	Antrum	History of radiation therapy (>50 Gy)
Floxuridine toxicity	Antrum and body	Hepatic artery infusion chemotherapy
Amyloidosis	Antrum	Systemic amyloidosis
MALIGNANT CONDITIONS		
Lymphoma	Localized or diffuse	May have generalized lymphoma
Carcinoma	Localized or diffuse	Associated narrowing and rigidity of stomach

TABLE
36-4

Gastric Narrowing

Cause	Radiographic Findings	Comments
BENIGN CONDITIONS		
Scarring from peptic ulcer disease	Smooth or asymmetric antral narrowing	History of ulcers
Atrophic gastritis	Diffusely narrowed, tubular stomach with decreased or absent folds	Pernicious anemia
Eosinophilic gastritis	Antral narrowing	Peripheral eosinophilia; history of allergic diseases
Crohn's disease	Funnel-shaped antral narrowing (ram's horn or shofar sign)	Associated Crohn's disease in small bowel or colon
Sarcoidosis	Cone-shaped antral narrowing	Pulmonary sarcoidosis
Tuberculosis	Antral narrowing; fistulas common	History of AIDS or travel to endemic areas
Syphilis	Funnel-shaped antral narrowing	Occurs in <1% of patients with syphilis
Caustic ingestion	Narrowing of antrum or antrum and body	History of caustic ingestion; esophageal scarring in 20%
Radiation	Antral narrowing	History of radiation therapy (>50 Gy)
Cytomegalovirus infection	Antral narrowing and ulceration	History of AIDS
Amyloidosis	Antral narrowing	Systemic amyloidosis
Antral diaphragm or web	Transverse weblike area of antral narrowing	May be asymptomatic
MALIGNANT CONDITIONS		
Scirrhous carcinoma	Linitis plastica	Antral narrowing classic, but isolated involvement of proximal stomach in 40%
Metastatic breast cancer	Linitis plastica	Recent or remote history of breast cancer
Omental cake	Mass effect and spiculated folds on greater curvature; occasionally circumferential	Omental metastases from ovarian carcinoma or other malignant neoplasms
Non-Hodgkin's lymphoma	Linitis plastica	May have generalized non-Hodgkin's lymphoma
Hodgkin's lymphoma	Linitis plastica	May have generalized Hodgkin's lymphoma
Kaposi's sarcoma	Linitis plastica	Homosexuals with AIDS; usually have Kaposi's sarcoma on skin

TABLE 36-5 Gastric Outlet Obstruction

Cause	Radiographic Findings	Comments
Peptic ulcer disease	Antral, pyloric, or duodenal ulcer with spasm, edema, or scarring	Difficult to differentiate from tumor if high-grade obstruction
Antral scarring	Antral narrowing	Crohn's disease, sarcoidosis, tuberculosis, syphilis, caustic ingestion, radiation
Carcinoma	Infiltrating antral or pyloric channel tumor	Usually advanced lesions
Other malignant tumors	Irregular narrowing or extrinsic compression of antrum or duodenum	Pancreatic carcinoma, lymphoma, retroperitoneal metastases
Hypertrophic pyloric stenosis	Elongated, narrowed pylorus	Uncommon cause of obstruction in adults
Antral diaphragm or web	Transverse, weblike area of antral narrowing	Degree of obstruction depends on size of central aperture of web
Gastric volvulus	Dilated, upside-down intrathoracic stomach	Surgical emergency if incarcerated or strangulated
Gastroparesis	Flaccid stomach with decreased or absent peristalsis but no gastric outlet obstruction	History of diabetes, narcotic use, or other conditions associated with gastroparesis

TABLE 36-6 Duodenal Filling Defects

Cause	Radiographic Findings	Comments
NON-NEOPLASTIC CONDITIONS		
Prolapsed antral mucosa	Mushroom-shaped defect at base of bulb	Usually asymptomatic
Flexural pseudotumor	Filling defect at superior duodenal flexure resulting from redundant mucosa	May simulate mass
Heterotropic gastric mucosa	Tiny, polygonal, or angulated nodules at base of bulb	No clinical significance
Brunner gland hyperplasia	Multiple rounded nodules in proximal duodenum (Swiss cheese appearance)	Associated with duodenitis
Benign lymphoid hyperplasia	Multiple tiny, rounded nodules in proximal duodenum	Associated with immunologic disorders
Choledochocoele	Submucosal mass in region of ampulla	Congenital anomaly
Duplication cyst	Submucosal mass on medial wall of descending duodenum	Congenital anomaly
Intramural hematoma	Submucosal mass on medial wall of duodenum	Bleeding diathesis, anticoagulation, or trauma
BENIGN TUMORS		
Polyps	Smooth, sessile elevations; usually solitary	Hyperplastic or adenomatous
Polypoid syndromes	Multiple polypoid lesions	Familial adenomatous polyposis, Peutz-Jeghers syndrome, Cronkhite-Canada syndrome, juvenile polyposis
Villous adenoma	Polypoid mass with frondlike projections; usually near ampulla	High malignant potential
Mesenchymal lesions	Submucosal mass, often with central ulceration or umbilication	Leiomyoma, lipoma, neurogenic tumor, Brunner gland hamartoma, ectopic pancreatic rest
MALIGNANT TUMORS		
Duodenal carcinoma	Polypoid mass at or distal to papilla of Vater	Gastrointestinal bleeding or obstruction
Ampullary carcinoma	Polypoid mass in region of ampulla	Jaundice common
Malignant gastrointestinal stromal tumor	Lobulated submucosal mass; ulceration or cavitation common	Better prognosis than carcinoma
Metastases	Multiple submucosal masses or bull's-eye lesions	Most commonly malignant melanoma or metastatic breast cancer
Lymphoma	Multiple submucosal masses or bull's-eye lesions	Usually non-Hodgkin's lymphoma
Kaposi's sarcoma	Multiple submucosal masses or bull's-eye lesions	Homosexuals with AIDS; usually have Kaposi's sarcoma on skin
Carcinoid	Multiple submucosal masses or bull's-eye lesions	Carcinoid syndrome uncommon

**TABLE
36-7****Thickened Duodenal Folds**

Cause	Radiographic Findings	Comments
Duodenitis	Thickened, nodular folds in proximal duodenum; occasionally associated with erosions	Not a reliable diagnosis unless folds grossly thickened
Brunner gland hyperplasia	Thickened, nodular folds in proximal duodenum	Usually associated with duodenitis
Chronic renal failure	Markedly thickened, nodular folds, particularly in bulb	Usually on dialysis
Pancreatitis	Thickened folds associated with medial compression or widening of duodenal sweep	Elevated serum amylase level; CT, MRI, or ultrasound for confirmation
Zollinger-Ellison syndrome	Thickened folds in stomach, duodenum, and proximal jejunum	Ulcers in atypical locations
Crohn's disease	Thickened folds, ulceration, or strictures	Associated Crohn's disease in small bowel or colon
Parasitic infection (giardiasis, strongyloidiasis)	Thickened or effaced folds, irritability, and spasm in duodenum and proximal jejunum	Stool cultures or small bowel brushings and biopsy specimens for diagnosis
Cryptosporidiosis	Thickened folds in duodenum and small bowel	History of AIDS; profuse secretory diarrhea
Celiac disease	Thickened folds in proximal duodenum	Often associated with bubbly bulb
Intramural hemorrhage	Thickened, spiculated folds or thumbprinting	History of bleeding diathesis, anticoagulation, or trauma
Varices	Serpentine folds in proximal duodenum	Portal hypertension
Lymphoma	Thickened folds or thumbprinting	Usually non-Hodgkin's lymphoma

**TABLE
36-8****Dilated Duodenum (Megaduodenum)**

Cause	Associated Radiographic Findings	Comments
Scleroderma	Dilated small bowel with hide-bound appearance	Systemic signs of scleroderma
Celiac disease	Dilated small bowel with decreased number of folds in jejunum	Malabsorption
Zollinger-Ellison syndrome	Thickened folds and increased secretions in stomach and duodenum; one or more ulcers	Hypergastrinemia
Strongyloidiasis	Thickened or effaced folds, ulceration, or lead pipe appearance in duodenum and jejunum	History of AIDS or travel to endemic areas
Superior mesenteric root syndrome	Broad, linear crossing defect on distal duodenum by mesenteric root	Thin or bedridden patients
Vagotomy	Dilated small bowel	Appropriate surgical history
Obstruction	Benign or malignant narrowing or extrinsic compression of duodenum	Postbulbar ulcer, Crohn's disease, pancreatitis, metastatic disease
Ileus	Dilated duodenum without mechanical obstruction	Postoperative ileus, metabolic imbalance, pancreatitis

**TABLE
36-9****Extrinsic Impressions on the Duodenum**

Cause	Location	Radiographic Findings	Comments
Pancreatic disease	Medial	Widened duodenal sweep	Pancreatitis, pancreatic pseudocyst, or pancreatic carcinoma
Peripancreatic adenopathy	Medial	Widened duodenal sweep	Peripancreatic metastases or lymphoma
Aortic aneurysm	Medial	Widened duodenal sweep	Aortoduodenal fistula is a rare complication
Gallbladder disease	Superior	Extrinsic compression of bulb or proximal duodenum	Acute or chronic cholecystitis or hydrops of the gallbladder
Liver disease	Superior	Extrinsic compression of bulb or proximal duodenum	Hepatomegaly of any cause
Renal disease	Posterolateral	Extrinsic compression of descending duodenum	Polycystic kidneys, renal cell carcinoma
Colonic disease	Anterolateral	Extrinsic compression of descending duodenum	Carcinoma of the hepatic flexure

Unexplained Gastrointestinal Bleeding

The focus of this chapter is on barium examinations of the mesenteric small intestine. Normal anatomy pertinent to understanding barium examinations is presented. The variety of contrast examinations for studying the small intestine is then described. Finally, a symptom-based approach to contrast imaging of the small intestine is presented.

Normal Small Intestine

The small intestine is extremely tortuous, beginning at the pylorus and extending about 11 feet in the living human from the pylorus to the ileocecal valve. Intestinal length is extremely variable, depending on neuromuscular tone and vascular flow. For example, the denervated, bloodless intestine stretched at autopsy varies from 10 to 30 feet.¹ A patient with a small bowel obstruction will have a tortuous, long, and wide small intestine in which the jejunum may fall deep into the pelvis.

The mesenteric portion of the small intestine is suspended from the retroperitoneum by the relatively short root of the small bowel mesentery, extending about 15 cm from the duodenojejunal junction to the right iliac fossa.² The mesenteric small intestine is divided into the jejunum and ileum. The jejunum arbitrarily comprises the proximal 40% of the mesenteric small intestine and the ileum makes up the distal 60% (Fig. 37-1). The jejunum typically occupies the left upper quadrant, and the ileum occupies the pelvis and right lower quadrant. The location of the jejunum and ileum is often variable, however, given the mobility of the intestine on the root of the mesentery. Not infrequently, the jejunum flops into the right upper quadrant or changes position during fluoroscopic examination of the small bowel.

The small intestine has a smooth curvilinear contour, as readily seen on abdominal radiographs or cross-sectional imaging studies in patients with free intraperitoneal air. The inner contour of the intestine is characterized by folds that encircle the lumen, known as the folds of Kerckring, valvulae conniventes, or plicae circulares (Fig. 37-2). These folds are composed of mucosa and submucosa (Fig. 37-3) and increase the surface area of the small intestine by 300%.¹ The small bowel folds lie perpendicular to the longitudinal axis of the intestine and are thicker, taller, and more numerous in the jejunum than in the ileum (Table 37-1).^{2,3} Villi are leaf- or finger-shaped protrusions of epithelium and lamina propria (see Fig. 37-3) that stud the surface of the folds. Each villus has a core of lamina propria containing a cellular stroma, capillaries, a lacteal, and nerves. Villi are tall and thin in the jejunum and shorter and broader in the ileum.¹ Duodenal villi are more variable and can be short and broad, leaf-shaped, or branched.¹ The villi are about 1 mm in cross section and are just at the limits of fluoroscopic resolution (Fig. 37-4). In contrast, the microvillous brush border of the small intestine is invisible on all radiographic examinations.

The small intestine is one of the largest immunologic organs of the body and a major site of interaction with foreign food antigens, pathogens, and toxins.⁴ The host defenses begin at the epithelial surface with a mucus layer containing immunoglobulins (especially secretory IgA) and enzymes. This mucus prevents microbes from adhering to the epithelium and acts as a buffer and lubricant.¹ A variety of other defenses also protect the host from these food antigens, including intraluminal gastric acid, bile salts, and pancreatic enzymes, and small bowel peristalsis.

The small bowel epithelium is composed of a single layer of cells bound by tight junctions impermeable to large molecules and pathogens. Intramucosal phagocytes include granulocytes, macrophages, and Paneth cells. Three distinct lymphocyte populations are present in the intestine within the epithelium, lamina propria, and Peyer's patches. Intraepithelial lymphocytes

Figure 37-1 Normal small intestine. Overhead radiograph from enteroclysis (small bowel enema) shows the jejunum (J) in the left upper quadrant and the ileum (I) in the right lower quadrant. The transverse colon is also seen (T). The folds are more numerous, taller, and slightly thicker in the jejunum than in the ileum. The jejunum can be up to 4 cm in diameter and the ileum up to 3 cm in diameter.

Figure 37-2 Normal small bowel folds. Spot image of the mid-small intestine from enteroclysis shows the folds as linear radiolucent filling defects (long black arrows) in the shallow barium pool. In contrast, nondependent folds are etched in white (short black arrows). The height of the folds (white arrow) indicates that this image was obtained from the distal jejunum–proximal ileum. The mucosal surface is smooth.

are located in the basal portion of the epithelium and comprise up to 30% of the cell population in the mucosa. Immunocytes in the lamina propria are composed mainly of IgA-secreting plasma cells and lymphocytes. T lymphocytes of helper-inducer and suppressor-cytotoxic types are present. Lymphoid

Figure 37-3 Portions of two small bowel folds are present on this histologic photomicrograph. Each fold (plica) is composed of a mucosal layer (M) (epithelium, lamina propria, and muscularis mucosae) covering a submucosal core (S). Each villus (arrow) is composed of a single layer of epithelial cells covering a core of lamina propria. The muscularis propria is composed of an inner circular muscle layer (C) and outer longitudinal muscle layer (L).

TABLE 37-1 Normal Parameters for Enteroclysis and Small Bowel Follow-Through		
Parameter	Enteroclysis	Small Bowel Follow-Through
NUMBER OF FOLDS PER INCH		
Jejunum	Four to seven	Difficult to count
Ileum	Two to four (or less)	Difficult to count
FOLD THICKNESS (MM)		
Jejunum	1-2	2-3
Ileum	1-1.5	1-2
FOLD HEIGHT (MM)		
Jejunum	3-7	Difficult to assess
Ileum	1-3	Difficult to assess
LUMEN WIDTH (CM)		
Jejunum	<4 cm	<3
Ileum	<3	<2

aggregates span the muscularis mucosae, with portions of these aggregates in the lamina propria and submucosa. These lymphoid aggregates increase in size and number in the distal ileum (Fig. 37-5), forming confluent Peyer’s patches in the lower ileum. A specialized epithelium that is one cell layer in thickness separates these lymphoid aggregates from the lumen, facilitating antigen processing. The lymphoid aggregates do not have a capsule, defined borders, a medulla, or afferent lymphatics that are present in lymph nodes.¹ The follicular areas are composed of B cells, and the parafollicular regions are composed of T cells.

Figure 37-4 Normal villi demonstrated by enteroclysis. Spot image of the jejunum shows villi in one loop as tiny, submillimeter, round radiolucent filling defects (*open arrows*). This loop can be identified as jejunum by the relatively tall height of the folds (*thin arrow*).

Figure 37-5 Lymphoid hyperplasia of the distal ileum caused by common variable immunodeficiency. Spot image of the distal ileum shows numerous 1- to 2-mm round or ovoid radiolucent filling defects in the shallow barium pool (*arrow*). These lymphoid follicles are more numerous and extend more proximally than usual. The ileal side of the ileocecal valve is identified (*I*).

Principles for Performing and Interpreting Small Bowel Examinations

The small intestine is a difficult structure to image. The intraluminal environment is hostile to barium preparations. A large amount of fluid (≈ 9 L) enters the small intestine each day, with only 1.5 to 1.9 L entering the colon.⁵ Bile acids, gastric acids, pancreatic secretions, and the epithelial mucus layer interact with barium in the small intestine. Fortunately, most modern barium suspensions no longer suffer from flocculation and clumping, as often occurred in the past.

Because of the inherent length and motility of the small intestine, imaging of this structure can take a long time. Intestinal loops overlap and change in size, shape, and position with peristalsis. Normal small bowel transit ranges from 30 to 120 minutes. The transit time can be lengthened dramatically in patients with obstruction or adynamic ileus from various causes.

The radiologist evaluates the overall location, course, and size of various portions of the small intestine.⁶ For example, the radiologist determines the location of the duodenojejunal junction and the location of the first loops of jejunum. The radiologist also evaluates the luminal contour and searches for abnormalities that extend beyond the small intestine (e.g., diverticula [Fig. 37-6], sacculations, ulcers, exoenteric masses) or lesions that protrude into the lumen (e.g., polyps [Fig. 37-7], abnormal folds). The small bowel folds are best evaluated when the lumen is fully distended, and the folds lie perpendicular to

Figure 37-6 Jejunal diverticula. Spot image from enteroclysis shows at least 10 small diverticula extending from the mesenteric border of a jejunal loop. Some diverticula are etched in white by barium (*white arrows*), and others are filled with barium (*black arrow*).

the longitudinal axis of the bowel. Fold width also depends on the degree of luminal distention; the greater the distention, the thinner the folds appear (Fig. 37-8). The folds are best shown after mucus has been washed off the luminal surface by the barium column. If folds are evaluated long after the barium column has passed, intestinal secretions can lift barium away

Figure 37-7 Carcinoid tumor in the ileum. Spot image of the distal ileum shows a 1.5-cm ovoid radiolucent filling defect (white arrow) protruding into the barium column. Note how the folds (black arrows) are pulled toward the tumor by a desmoplastic reaction at the base of the lesion. A second small carcinoid tumor is seen (open arrow). This desmoplastic reaction is typical of carcinoid tumors or intraperitoneal metastases.

from the mucosal surface so that the folds may erroneously appear thickened. En face mucosal detail is seen during compression of the barium column or with double-contrast technique. Visualization of this mucosal detail is necessary for detecting mucosal granularity or nodularity or small ulcers, such as aphthoid ulcers (Fig. 37-9).

Fluoroscopy is a key component of any small bowel examination. The radiologist examines the head of the barium column to understand the course of the small intestine and to detect contour abnormalities or filling defects in the barium column. The radiologist also assesses bowel motility, distensibility, and pliability during the fluoroscopic examination. Fixation of intestinal loops can also be recognized by manual palpation of the bowel.

Small Bowel Follow-Through

There are many ways to perform a small bowel follow-through examination. In this chapter, I discuss the technique that I use. A small bowel follow-through is a single-contrast examination of the esophagus, stomach, and small intestine that uses barium most appropriate for the small bowel. For this examination, the patient drinks a large volume (500-1000 mL) of low-density (30%-50% w/v) barium specifically designed for evaluating the small intestine.

The patient should not eat or drink after 9 to 11 PM the day before the examination. If a peroral pneumocolon is to be performed, the patient should receive a barium enema preparation to cleanse the terminal ileum and right side of the colon.

A single-contrast upper gastrointestinal (GI) series is often performed (using 1-2 cups of low-density barium) as a prelude to examining the small bowel. The purpose of the upper GI series is to show gross upper GI involvement by diseases that affect the small bowel, such as Crohn's disease and scleroderma. Esophageal or gastric abnormalities may also be detected as incidental findings, given the high frequency of upper GI

Figure 37-8 Variation in the width of small bowel folds with luminal distention. **A.** Spot image obtained during early single-contrast phase of enteroclysis shows a focal area of tapered narrowing (medium-sized arrow) containing an irregular collection of barium (long arrow). Note apparent widening of the small bowel folds (short arrow) when the lumen is incompletely distended. **B.** Spot image obtained during early phase of methylcellulose filling (the loop is still visualized mainly in single contrast before a transradiant methylcellulose effect has been achieved) shows how the narrowed segment has a more abrupt proximal margin (long black arrow). An amorphous collection of barium (white arrow) disrupts the normal luminal contour and fold pattern. This was an ulcerated adenocarcinoma of the distal jejunum causing low-grade small bowel obstruction. Note the normal width of the small bowel folds (short black arrow) in the distended jejunum proximal to the tumor.

Figure 37-9 Aphthoid ulcers in Crohn's disease. Spot image of the terminal ileum from a peroral pneumocolon shows aphthoid ulcers (arrows) as punctate barium collections surrounded by radiolucent halos of edema.

disorders such as gastroesophageal reflux disease. However, a double-contrast upper GI examination using high-density barium is not performed, because this barium is not designed for evaluating the small intestine and, if used, high-density barium often prevents adequate visualization of pelvic small bowel loops. The radiologist therefore sacrifices double-contrast evaluation of the upper GI tract to ensure a more optimal examination of the small intestine. After the esophagus, stomach, and duodenum are evaluated, the patient leaves the fluoroscopic suite and slowly sips an additional 1 to 2 cups of low-density barium.

In some practices, a technologist obtains overhead radiographs and a radiologist evaluates the overheads views, only fluoroscopy and palpating the small bowel when an abnormality is suspected or when barium has reached the terminal ileum. Such an approach is strongly discouraged. A small bowel follow-through relies on fluoroscopic detection and spot image documentation of all abnormalities. Each loop of small bowel is palpated when it is optimally distended by low-density barium (Fig. 37-10). The radiologist should therefore evaluate the patient at least several times—about 15 to 30 minutes after the single contrast upper GI series is performed and then at 15- to 45-minute intervals, depending on how fast the barium column is progressing through the small intestine. The patient is turned into various positions, and manual palpation (including supine, lateral, and prone compression views) is used to splay out individual small bowel loops. In my practice, I no longer obtain overhead radiographs. If the big picture is required, a digital spot radiograph obtained at the lowest magnification is usually adequate for this purpose.

Figure 37-10 Normal small bowel follow-through. Spot radiograph with compression shows the distal jejunum. When the loops are well distended (D) and separated from each other, an image from a small bowel follow-through is comparable to that from enteroclysis. When loops are overlapping (black O), however, the density of the barium may obscure anatomic detail. When loops are overlapping and partially collapsed, the overlapping folds may form a feathery pattern (white O).

The length of the examination can be shortened by administering a standard dose of 20 mg of metoclopramide (Reglan) orally 20 to 30 minutes before the study or 10 mg intravenously at the beginning of the examination.⁷⁻⁹ Metoclopramide accelerates gastric emptying and small bowel transit. Unfortunately, metoclopramide also increases resting muscle tone, resulting in incomplete small bowel distention.¹⁰ The result is a faster but less optimal examination.

Some radiologists administer two to three doses of effervescent agent (600-900 mL of CO₂) when the barium column reaches pelvic loops of ileum or the terminal ileum. This technique shortens the examination and demonstrates small bowel loops on an air-contrast study. Nevertheless, administration of an effervescent agent can be uncomfortable because large volumes of gas can incite intestinal cramping. It also results in decreased luminal distention in comparison to enteroclysis, and only one third to one half of the small bowel is shown on the air-contrast study.¹¹

Some radiologists use a premade mixture of 24% w/v barium suspended in methylcellulose. This barium suspension produces greater luminal distention than a routine small bowel follow-through, as well as a transradiant effect that mimics enteroclysis.¹² However, the barium is not as dense as that used for a routine small bowel follow-through so it can be more difficult to detect filling defects in the barium column. Luminal distention is also less than that in

Figure 37-11 Partially distended small bowel during small bowel follow-through. Folds (F) in a partly distended proximal ileal loop have a feathery pattern. The contour is well visualized (open arrow) when a loop is isolated. When loops are contracting (short arrow), a smooth impression is seen on the mesenteric border, mimicking an extrinsic lesion indenting the small bowel. When a loop is collapsed or contracting, folds lie parallel to the longitudinal axis of the small bowel (long arrow). Dense areas of barium may result from overlapping loops (black O) that can be separated by compression.

enteroclysis, because it is limited by the rate of gastric emptying at the pylorus.

The small bowel follow-through has two important limitations. Even with the use of metoclopramide, the pylorus delays emptying of barium from the stomach so the small bowel may be incompletely distended. As a result, it can be difficult to evaluate luminal contour (Fig. 37-11) or detect filling defects in the barium column. Because normal transit time for the small bowel is 30 to 120 minutes, it also is not feasible for the radiologist to remain in the fluoroscopy suite for the entire examination. As a result, the small bowel can only be evaluated intermittently, and lesions can be missed, depending on the degree of filling and distention of individual small bowel loops at the time of fluoroscopy.

PERORAL PNEUMOCOLON

A peroral pneumocolon may be performed in conjunction with a small bowel follow-through.¹³⁻¹⁶ This is a double-contrast examination, primarily used to evaluate patients with suspected Crohn's disease in the terminal ileum or evaluate the right side of the colon in patients in whom a barium enema or colonoscopy failed to visualize this portion of the bowel adequately.

The patient undergoes a barium enema preparation to clear feces from the terminal ileum and right side of the colon. After a routine small bowel follow-through has been performed, 1 mg of glucagon is administered intravenously, and air is insufflated into the rectum via a Foley catheter. The colon is slowly distended with air as the patient is turned into various positions to manipulate air into the cecum and terminal ileum. Air can be refluxed successfully into the terminal ileum in 85% to 90%

Figure 37-12 Normal distal ileum demonstrated during peroral pneumocolon (arrows). Spot radiograph shows the terminal ileum (T) and distal ileum (white I) in an air-contrast study. The mucosa is smooth and featureless. The ileal folds (arrows) are of normal thickness. The cecum (C) and ileal side of the ileocecal valve (black I) are also identified.

of patients. Double-contrast spot images of the pelvic ileum, terminal ileum, and right side of the colon are then obtained (Fig. 37-12).

Enteroclysis

The small intestine has been examined via intubation techniques since the 1920s.¹⁷⁻²⁰ All these techniques entail positioning a tube beyond the pylorus, overdistending the small bowel with various contrast agents, and detecting abnormalities at fluoroscopy. The multiplicity of techniques for performing enteroclysis reflects the imperfections of each individual technique. Lack of universal acceptance of this procedure by the radiologic community is related to the relatively high level of expertise needed to perform enteroclysis and to patient discomfort during the intubation procedure.

PREPARATION

An unprepped patient often has feces in the terminal ileum and right side of the colon. This fecal matter obscures mucosal detail, mimics polyps, and impedes passage of contrast material through the distal ileum.²¹ A preparation is therefore given to clear feces from the terminal ileum and right colon before the examination. This can be a full barium enema-type preparation, including osmotic cathartics such as magnesium citrate and colonic stimulants such as bisacodyl. At my institution, I have achieved successful cleansing of the right side of the colon with a clear liquid diet the day before the examination

Figure 37-13 Value of metoclopramide for evaluating narrowing of the terminal ileum in a patient with Crohn's disease. **A.** Spot radiograph from a small bowel follow-through shows a stringlike segment of narrowing (arrows) in the terminal ileum inferior to the cecum (C). **B.** After metoclopramide has been administered, the narrowed segment (short arrows) distends considerably but is still abnormal, with effaced folds and nodular mucosa caused by Crohn's disease. An ileoileal fistula (open arrows) is also visualized. These images show how narrowing in Crohn's disease may be caused by a combination of spasm, edema, inflammatory change, and fibrosis.

combined with four 5-mg tablets of bisacodyl given the evening before the examination. The patient does not eat or drink after midnight. On the day of the examination, the patient should temporarily discontinue medications such as narcotics that decrease small bowel peristalsis.

METOCLOPRAMIDE

Metoclopramide is administered orally or intravenously before the examination.^{21,22} Metoclopramide begins to take effect 1 to 3 minutes after intravenous (IV) injection of a 10-mg dose or 30 to 60 minutes after ingestion of two 10-mg tablets.²³ This drug facilitates passage of the enteroclysis catheter by relaxing the pyloric sphincter and duodenal bulb and by increasing gastric antral contractions.^{24,25} Passage of barium through the small bowel is accelerated because metoclopramide increases peristalsis in the duodenum and jejunum. Metoclopramide may also improve visualization of strictures in Crohn's disease (Fig. 37-13). However, its use is contraindicated in patients with known pheochromocytomas because it may stimulate catecholamine release from these lesions, precipitating a hypertensive crisis.²⁶ It is also contraindicated in patients with epilepsy or patients receiving drugs that may cause extrapyramidal reactions because it increases the frequency and severity of seizures associated with these reactions.

ANESTHESIA

The major complaint that patients have about enteroclysis is intubation. Patients can be made more comfortable by the use of conscious sedation.²⁷ One protocol for conscious sedation includes a combination of fentanyl or diazepam for analgesia and midazolam for an amnesic effect.²¹ Oral diazepam alone can be used as an alternative.²⁴

INTUBATION

A variety of enteroclysis catheters are available from several manufacturers.²⁸⁻³⁰ The catheters have a diameter of 8 to 13 F, an end hole or side holes, and a balloon attached to their tips.

One manufacturer has a multiple-lumen catheter capable of a diagnostic study and therapeutic decompression.³¹

I suggest having the patient ingest a small amount (15-30 mL) of enteroclysis barium orally before intubation. This barium coats the antrum, pylorus, and duodenal bulb, which are important landmarks that guide the radiologist in passing the enteroclysis catheter.

A complete description of intubation techniques is beyond the scope of this chapter, but is described in several references.^{6,21,22,24} The enteroclysis catheter can be passed into the oropharynx via an oral or nasal route. The oral route has the advantage of allowing visualization of catheter passage into the throat but the disadvantage of causing more gagging. Oral intubation is made easier by the use of a topical anesthetic spray. In contrast, the nasal route causes less gagging because there is less contact of the catheter with the base of the tongue and posterior pharyngeal wall. However, nasal intubation may cause nasal bleeding and may result in prolonged nasal discomfort as the catheter is manipulated during the examination. Nasal intubation is made easier with the use of topical lidocaine jelly in the intubated naris.

The major purpose of the catheter guidewire is to torque or guide the tip of the catheter along the longitudinal axis of the bowel. The guidewire is sometimes placed at the tip of the catheter, with appropriate torquing to guide the catheter in the proper direction. At other times, the guidewire is retracted, allowing the soft tip of the catheter to pass through sensitive regions, such as the pylorus, or to curve around tight bends, such as the apex of the duodenal bulb (Fig. 37-14). Passage of the catheter into the duodenum is also facilitated by changing the configuration of the bowel with manual compression (Fig. 37-15) or by turning the patient on the fluoroscopic table. The tip of the catheter can be left in the second portion of the duodenum for single-contrast or air-contrast enteroclysis. When methylcellulose is used, however, the tip of the catheter should ideally be placed in the first loop of jejunum to limit reflux of methylcellulose into the stomach. Inflation of the balloon on the catheter also helps prevent methylcellulose from refluxing into the stomach. If the patient complains of discomfort during inflation of the balloon, it should immediately be deflated until

Figure 37-14 Enteroclysis catheter directed around the apex of the duodenal bulb. The soft tip of the enteroclysis catheter is bending around the 180-degree turn (thick arrow) between the duodenal bulb and proximal descending duodenum. The wire (thin arrow) has been retracted, allowing the catheter tip to be more pliable so that it can bend around this curve. Contrast in the duodenum (D) is the residue of 30 mL of barium swallowed at the outset of the study to outline the anatomy of the pyloric region and facilitate passage of the catheter.

Figure 37-15 Compression by examiner to guide the enteroclysis catheter. The hand of the examiner covered by a lead glove (arrow) pushes on the greater curvature of the stomach. This directs the enteroclysis catheter toward the pylorus. Note how the guidewire is retracted from the tip of the catheter.

the discomfort subsides. Duodenal perforation was reported in one patient during intubation for enteroclysis.³²

Successful intubation during enteroclysis depends on the skill and experience of the examining radiologist, whether or not sedation is used, and the patient's anatomy. Intubation is more difficult in patients with a prominent cricopharyngeus, hiatal hernia, and transversely oriented stomach. Intubation is also potentially more difficult in patients with a dilated atonic stomach resulting from diabetes or other causes.

Contrast material can be infused through the enteroclysis catheter with syringes or a variety of pumps. The use of an electric pump (e.g., a minidialysis pump, RS-7800; Renal Systems, Minneapolis) enables the radiologist to control the infusion rate accurately, which can be adjusted during the examination.³³ If the infusion rate is too fast, overdistention of the jejunum may cause hypotonia of the bowel. If the infusion rate is too slow, however, the lumen may be suboptimally distended, prolonging the examination time. Flow rates are generally between 50 and 150 mL/min.

The following descriptions of the various types of enteroclysis reflect my experiences with these techniques. Each radiologist should carefully evaluate the advantages and disadvantages of each before choosing a particular method for performing enteroclysis.

SINGLE-CONTRAST ENTEROCLYSIS

A low-density (20%-40% w/v) barium is the usual contrast agent for single-contrast enteroclysis.^{25,34} In rare cases of

suspected perforation, water-soluble contrast agents (e.g., meglumine diatrizoate, diatrizoate sodium) can be used. The enteroclysis catheter is passed into the proximal duodenum. Contrast is instilled via a syringe, pump, or gravity feed bag. Between 600 and 1200 mL of barium are injected at an initial rate of about 75 mL/min. After administering a large volume of barium, water may be instilled into the catheter to push barium into the distal ileum and obtain a moderate double-contrast effect.

Single-contrast studies are simpler to perform than other types of enteroclysis because only one contrast agent is used. Reflux of barium into the stomach rarely induces vomiting, as sometimes occurs with methylcellulose. With an air- or methylcellulose-contrast technique, the mucosal surface of the small bowel is readily demonstrated en face. With single-contrast technique, however, evaluation of mucosal detail en face depends on compression and analysis of fold morphology. Although single-contrast technique is inferior to double-contrast techniques for visualizing mucosal detail, the diagnosis of many small bowel abnormalities (e.g., adhesions, tumors, hernias) does not require subtle demonstration of surface detail. In patients with known or suspected malabsorption, however, double-contrast enteroclysis techniques are recommended.

AIR-CONTRAST ENTEROCLYSIS

Air contrast is the standard form of enteroclysis in Japan and has become a favorite technique of Dr. Dean Maglinte, one of the leading proponents of enteroclysis.^{21,35-37} I have used the technique at one of my institutions, where an electric pump was

Figure 37-16 Jejunum during air-contrast enteroclysis. Coned-down view from an overhead radiograph demonstrates the small intestine in an air-contrast study. The jejunum (J) is well shown where loops are seen without overlap. When loops overlap (O), however, the small bowel is not optimally visualized.

Figure 37-17 Too much barium on air-contrast enteroclysis. Mid-small bowel loops are well visualized (J) in some areas. In other areas, however, dense barium (D) obscures folds and mucosal detail. It is sometimes difficult to titrate the appropriate volume of barium for air-contrast enteroclysis.

not available for methylcellulose infusion. After intubation of the proximal duodenum, between 300 and 600 mL of barium varying from 40% to 80% w/v is instilled by gravity, syringe, or pump. The infusion rate of barium is altered to preserve peristalsis and for uniform distention of the proximal and mid-small bowel. Room air or carbon dioxide is administered when barium reaches the pelvic small bowel²¹ or terminal ileum.³⁷ Small bowel hypotonia may be induced by IV injection of 1 mg of glucagon after barium has reached the right side of the colon.⁶

Air-contrast enteroclysis produces spectacular mucosal detail in loops coated by barium and distended by gas (Fig. 37-16). However, I have found it difficult to titrate the amount of barium necessary to coat the bowel without having too much barium in the lumen. Unlike double-contrast studies of the stomach and colon, it is more difficult to manipulate the barium pool so some loops are visualized only with dense barium, despite using various patient positions and compression (Fig. 37-17). Overlap of barium-filled loops with air-filled loops also results in radiographic overexposure of the loops demonstrated in air contrast. Distention of pelvic loops with air is sometimes incomplete.

Another disadvantage of air-contrast enteroclysis is that injection of large volumes of air into the small intestine may cause considerable discomfort. Sedation of these patients is therefore strongly recommended by some authors.²¹

In summary, I have achieved beautiful demonstration of the jejunum but suboptimal demonstration of pelvic ileal loops with air-contrast enteroclysis. Air-contrast techniques are more likely to be of value for patients with intestinal disease involving long segments of small bowel (e.g., malabsorptive state, Crohn's disease). Methylcellulose-contrast enteroclysis is more effective,

however, for patients with adhesions or other lesions involving shorter segments of bowel.

METHYLCELLULOSE-CONTRAST ENTEROCLYSIS

During methylcellulose-contrast enteroclysis, a small volume of barium is propelled through the small intestine by a large volume of radiolucent liquid (the methylcellulose; Fig. 37-18).^{22,38} Medium-density (40% to 80% w/v) barium coats the intestinal mucosa, and methylcellulose distends the lumen. This is a biphasic examination. The radiologist follows the column of barium, looking for obstructing lesions (see Fig. 37-8) or lesions in the barium pool (Fig. 37-19). The small bowel folds and en face mucosal detail are then evaluated when the lumen is distended by methylcellulose. Full luminal distention by methylcellulose straightens the valvulae conniventes, better delineates en face mucosal detail, and overdistends the lumen, increasing conspicuity of low-grade obstructing lesions.

Varying amounts and densities of barium have been used for methylcellulose-contrast enteroclysis. I routinely use 220 to 300 mL of 80% w/v barium, infusing barium at 60 to 80 mL/min via a syringe until about half of the expected intestinal loops are visualized. Herlinger and associates use 180 to 220 mL of 80% w/v barium.²⁴ Maglinte and colleagues recommend infusing 300 to 600 mL of 50% w/v barium until pelvic loops of the ileum are filled.³⁹ The amount of barium infused for this examination ultimately depends on the perceived length and diameter of the small intestine and on the presence or absence of obstruction or increased intraluminal fluid.

The use of methylcellulose enables the radiologist to see through overlapping small bowel loops to a greater degree than that allowed with single-contrast or air-contrast enteroclysis.

However, methylcellulose-contrast enteroclysis also has several disadvantages. Methylcellulose is a thick sticky substance that may require dilution in the “barium kitchen.” Bubbles will form if methylcellulose is shaken, not stirred. Unless an electric pump is used, methylcellulose is messy and difficult to instill. The enteroclysis catheter tip should be placed in the jejunum because reflux of methylcellulose into the stomach may induce projectile vomiting. If the radiologist needs to visualize the duodenum, the catheter should therefore be retracted to the proximal duodenum at the end of the examination and additional barium infused (Fig. 37-20). Once methylcellulose has reached the

Figure 37-18 Methylcellulose-contrast enteroclysis. Overhead radiograph obtained at the end of the enteroclysis examination shows exquisite anatomic detail in nonoverlapping loops (S). Anatomic detail may be difficult to visualize, however, when loops overlap (O), even though the methylcellulose allows partial visualization of these overlapping loops, termed a *transradiant effect*.

colon, uncontrollable diarrhea may ensue, requiring placement of an enema tip in the rectum to allow rectal drainage and alleviate patient discomfort and embarrassment.

Methylcellulose-contrast enteroclysis almost always results in excellent double contrast in the jejunum. With infusion of enough methylcellulose, a double-contrast examination of the terminal ileum may also be achieved (Fig. 37-21). However, barium diffusion into the methylcellulose may result in a poor double-contrast effect in the ileum, resulting in only a single-contrast examination of the distal ileum (Fig. 37-22). To prevent diffusion of barium into the methylcellulose, the radiologist limits compression, especially in pelvic loops of the ileum. Thus, the double-contrast barium enema and peroral pneumocolon are more reliable techniques if a detailed double-contrast examination of the terminal ileum is required.

HYPOTONIC DUODENOGRAPHY

Hypotonic duodenography is a detailed examination of the duodenum and, in some patients, the first two loops of jejunum.⁶ This examination is used to elucidate confusing radiographic, computed tomography (CT), or endoscopic findings in the duodenum and first loop of the jejunum. High-density barium is administered via an enteroclysis catheter placed in the proximal descending duodenum. After high-density barium has entered the duodenum and first jejunal loop, the patient is rotated on the fluoroscopic table to coat the mucosa. A standard dose of 1 mg of glucagon is administered intravenously to induce intestinal hypotonia. Air is then injected into the catheter to distend the duodenal lumen, and spot images are obtained (Fig. 37-23).

A similar examination can be performed less invasively by having the patient swallow an effervescent agent and high-density barium. The patient is then placed with the right side down. When the duodenum has adequately filled with barium, 1 mg of glucagon is injected IV to induce intestinal hypotonia. The patient is then rotated on the table to coat the mucosa, and spot images are obtained. This technique is limited, however, because there is less control over the volume of barium and air

Figure 37-19 Metastatic melanoma demonstrated during enteroclysis. **A.** Spot image obtained during the single-contrast phase of enteroclysis shows a polypoid mass as a lobulated radiolucent filling defect (long black arrow) in the barium column. The normal luminal contour is disrupted (white arrow). A central barium collection is seen (short black arrow). **B.** Spot radiograph obtained during the methylcellulose phase again shows a slightly lobulated radiolucent filling defect (long arrow), with a central barium collection (short arrow), representing an ulcer. Apart from the ulceration, the surface of the polyp is smooth, indicating the submucosal origin of the lesion.

Figure 37-20 Air-contrast examination of duodenum after enteroclysis. Spot radiograph shows multiple small polyps (several identified by open black arrows) as radiolucent filling defects in the shallow barium pool on the posterior wall of the descending duodenum. The papilla of Vater is enlarged (open white arrows). Contrast in the colon (C) partly obscures the third portion of the duodenum. This patient had familial adenomatous polyposis syndrome. The polyps were tubular adenomas; the enlarged papilla of Vater resulted from an adenocarcinoma arising in a tubulovillous adenoma.

in the duodenum with the oral route than with the intubation technique.

Small Bowel Studies Using Water-Soluble Contrast Agents

The small intestine is a hostile environment for imaging with water-soluble contrast agents. These hyperosmolar agents draw fluid into the intestinal lumen and are further diluted by excess fluid in the lumen in patients with hypotonia or obstruction. As a result, the radiographic density of water-soluble contrast agents is generally inadequate for diagnostic purposes in patients with small bowel obstruction. These contrast agents are therefore not indicated for examining the small bowel, except in patients with suspected leaks.

In general, leaks arising in the duodenum or first several loops of jejunum can be demonstrated by water-soluble contrast studies. Leaks in the mid- or distal small bowel, however, are often missed because of dilution of the water-soluble contrast agent with fluid. When a leak is suspected in the distal small bowel (particularly at an ileocolic anastomosis), it may therefore be preferable to perform a water-soluble

Figure 37-21 Crohn's disease demonstrated by enteroclysis. Spot image shows thickened nodular folds (arrows) in the terminal ileum.

Figure 37-22 Diffusion of barium into methylcellulose column in neoterminal ileum in Crohn's disease. Spot image shows tapered narrowing of the neoterminal ileum (arrows), with minimal nodularity of the mucosa (n). The neoterminal ileum is seen only in single contrast, whereas a double-contrast effect (m) is seen more proximally. This patient underwent prior resection of the terminal ileum, cecum, and proximal ascending colon for Crohn's disease. This image shows recurrent Crohn's disease in the neoterminal ileum.

Figure 37-23 Hypotonic duodenogram. Upper endoscopy revealed a polypoid lesion in the duodenum. A radiographic study was requested for clarification. Spot image of the distal duodenum in air-contrast study shows a 1.8-cm polypoid lesion (*thin arrows*) etched in white in the second portion of the duodenum. A 2-cm polypoid lesion (*thick arrow*) is also seen at the junction of the third and fourth portions of the duodenum. Repeat endoscopy with biopsy and subsequent surgery revealed an adenocarcinoma of the second portion of the duodenum and a hemangioma of the fourth portion.

contrast enema with reflux of contrast medium into the distal ileum.

Suspected leaks in the mid–small bowel initially may be evaluated by CT. If the small bowel is not dilated, enteroclysis using water-soluble contrast may then be performed (Fig. 37-24).⁶

Retrograde Examinations of the Small Intestine

BARIUM ENEMA

The barium enema is an underused but powerful examination for imaging the terminal ileum and distal small bowel.⁴⁰ If plain abdominal radiographs or CT cannot differentiate a distal small bowel obstruction from an adynamic ileus, a single-contrast barium enema may be extremely helpful in these patients. The study can be used not only to rule out an obstructing lesion in the colon as a cause of dilated small bowel but also to evaluate the distal ileum by refluxing barium through the ileocecal valve. Reflux of barium into a dilated terminal ileum indicates the presence of an adynamic ileus, whereas reflux of barium into a narrowed terminal ileum (with dilated, gas-filled ileal loops more proximally) indicates the presence of a small bowel obstruction. In many cases, barium can be refluxed in a retrograde fashion to the site of transition, enabling the radiologist to determine the site and cause of obstruction (see Chapter 46). In patients with high-grade small bowel obstruction, a barium enema is faster and easier on the patient than an enteroclysis examination or small bowel follow-through.

A single-contrast or double-contrast barium enema may be performed in patients with suspected Crohn's disease.

Figure 37-24 Enteroclysis using water-soluble contrast. Spot image from water-soluble contrast enteroclysis shows a normal proximal fold pattern (l). When the small bowel is not distended, a study using water-soluble contrast can demonstrate anatomic detail. When the small bowel is hypomotile or distended, however, intraluminal fluid dilutes the water-soluble contrast, limiting visualization of the bowel.

Figure 37-25 Barium enema demonstrating recurrent Crohn's disease. On previous endoscopy, it was not possible to pass the endoscope through the ileocolic anastomosis into the neoterminal ileum in a patient who had prior surgery for Crohn's disease. A double-contrast barium enema shows a short stricture (*large arrow*) at the ileocolic anastomosis. Aphthoid ulcers (*small arrows*) are also seen in the adjacent neoterminal ileum.

Double-contrast studies have the advantage of being able to diagnose early inflammatory lesions of Crohn's disease, such as aphthoid ulcers (Fig. 37-25). However, single-contrast studies are more reliable for refluxing large volumes of barium into the distal small bowel when it is important to assess the terminal ileum and distal ileum for radiographic signs of Crohn's disease.

In patients who are not obstructed, a standard barium enema preparation may be helpful. However, in patients with high-grade small bowel obstruction, an oral preparation is contraindicated. Such studies should be performed without any preparation or after gentle cleansing enemas.

A standard dose of 1 mg of glucagon is administered IV to relax the colon and ileocecal valve. Up to 2.5 L of 20% to 30% w/v barium is instilled via an enema bag or tip. Reflux of barium through the ileocecal valve is possible in about 85% of patients. If a distal small bowel obstruction is present, an attempt should be made to reflux barium directly to the site of obstruction. In some cases, water can be added to the enema bag to propel the barium retrograde through the distal ileum.

ILEOSTOMY ENEMA

The small bowel proximal to an ileostomy can easily be evaluated by a retrograde examination through the ileostomy stoma. If there is clinical suspicion of a leak or obstruction, no preparation is used. If there is clinical suspicion of recurrent Crohn's disease, however, an oral preparation (e.g., magnesium citrate, Phospho-Soda) may be helpful for eliminating debris from the small bowel before performing the examination. The patient is also instructed not to eat solids the day before the procedure.

A soft catheter (e.g., Foley catheter) is inserted into the ileostomy. If disease is suggested at the ileostomy or near the peritoneal reflection (e.g., Crohn's disease, stricture, leak), the balloon of the catheter should not be inflated. If injection of barium shows no evidence of disease in the distal ileum at or near the peritoneal reflection, the catheter balloon may be inflated with 3 to 5 mL of air or saline, and the catheter is retracted to the peritoneal reflection. If there is doubt about disease at the ileostomy, the opening can be explored with a small finger. If inflation of the balloon is contraindicated, and barium leaks out from the ileostomy stoma, the radiologist can withdraw the catheter, distend the balloon outside the ostomy, and push the distended balloon against the outside of the ileostomy to seal the ileostomy opening.

A wide variety of contrast agents can be injected via the catheter. If a leak from the distal small bowel is suspected, water-soluble contrast agents may be used. If a distal small bowel obstruction is suspected, a single-contrast ileostomy enema can be performed with 30% to 50% w/v barium. Thin barium is injected via a syringe until the site of obstruction is reached and characterized. If Crohn's disease or tumor is suspected, a double-contrast ileostomy enema can be performed by first injecting 40% to 80% w/v barium into the proximal ileum, followed by air or methylcellulose to visualize mucosal detail (Fig. 37-26). As with all small bowel studies, fluoroscopy and spot images are the mainstays of diagnosis. The ileostomy and small bowel adjacent to the anterior abdominal wall are best visualized with the patient in a lateral position. The ileostomy is best filled after the catheter is removed, the ostomy bag is replaced, and the patient is turned to an orthogonal position (usually a steep oblique or lateral position).

Choice of Fluoroscopic Examination

Zealots of enteroclysis, small bowel follow-through, CT, CT enteroclysis, magnetic resonance (MR) enteroclysis, and capsule enteroscopy abound. This section attempts to provide a rational approach to fluoroscopic imaging of the small bowel.

The unifying feature of all forms of barium diagnosis is palpation of each loop of small intestine when the loop is optimally distended. This necessitates that the radiologist remain with the patient during enteroclysis or return to the fluoroscopic suite at 15- to 30-minute intervals for small bowel

Figure 37-26 Ileostomy enema. This patient complained of abdominal pain and distention. A total colectomy had previously been performed. CT revealed a dilated small bowel. An overhead radiograph obtained at the end of a retrograde ileostomy enema shows diffuse dilation of small bowel to the level of the proximal jejunum (j). No site of narrowing or obstruction is identified in this patient with an intestinal adynamic ileus. Air-contrast effect in the ileum (i) results from air present in the small bowel before barium was instilled via the ostomy (o).

follow-through studies, depending on the rate of progression of barium through the small intestine. Because of emphasis on fluoroscopic and spot image diagnosis, enteroclysis is associated with only a slightly higher radiation dose to the patient than small bowel follow-through.⁴¹ A single-contrast examination evaluates the luminal contour and filling defects in the barium column. A double-contrast examination evaluates the luminal contour, filling defects in the barium column or pool, and mucosal detail en face. The small bowel folds are well evaluated by either technique only when the lumen is fully distended.

The major advantage of the small bowel follow-through over enteroclysis is that it is easier on the patient and avoids the need for intubation of the small intestine, so that sedation is unnecessary. Long segments of abnormal bowel are easy to visualize (Fig. 37-27) as long as frequent fluoroscopy is performed. As a result, diseases involving long segments of small bowel, such as Crohn's disease, ischemia, and radiation changes, are readily detected on small bowel follow-through. However, enteroclysis has a number of important advantages over the small bowel follow-through. Because the radiologist is at the patient's side for the entire examination, fluoroscopy can be performed whenever needed. During enteroclysis, the pylorus also is bypassed, so that radiographic contrast agents can be instilled at an optimal rate for obtaining luminal distention. Short

Figure 37-27 Long segment of radiation enteropathy demonstrated by small bowel follow-through. **A.** Spot image shows abnormal loops of ileum (between *long arrows*). The folds are thickened but retain their normal orientation perpendicular to the longitudinal axis of the small bowel. Two areas of angulation (*short arrow*) are identified as a result of radiation serositis. No obstruction was seen. **B.** CT scan shows marked wall thickening (*long white arrow*) in a loop of ileum. Mild fold thickening is seen more proximally (*black arrow*). Note the normal wall thickness (*short white arrow*) in small bowel proximal to the diseased segment. Little anatomic detail is available in some loops (i).

Figure 37-28 Mesenteric border ulcer demonstrated on enteroclysis in patient with Crohn's disease. Spot image shows a thin linear collection of barium (*long arrows*) along the mesenteric border of the distal ileum. Folds (*short arrow*) are pulled toward the site of ulceration, leading to sacculization (*arrowheads*) of the relatively uninvolved antimesenteric border.

lesions such as tumors or skip lesions in Crohn's disease are better demonstrated by enteroclysis because the lumen is over-distended, making subtle areas of focal narrowing more conspicuous (see Fig. 37-7). The small bowel folds are also better evaluated by enteroclysis because the lumen is distended, and the folds are straightened.⁴² Major mucosal abnormalities such as cobblestoning can be demonstrated on single-contrast small bowel follow-throughs with compression, but demonstration of subtle mucosal abnormalities requires double-contrast technique (Fig. 37-28).

The choice of which radiographic study to perform (small bowel follow-through vs. enteroclysis) depends primarily on the indication for the examination. Various clinical settings for evaluating the small bowel are discussed in the following sections.

CHRONIC DIARRHEA

Small bowel follow-through is an adequate examination for the diagnosis of Crohn's disease or other inflammatory diseases involving long segments of bowel.²⁴ In general, a small bowel follow-through can demonstrate cobblestoning, mesenteric border ulcers, fissures, fistulas (Fig. 37-29), and long segments of narrowing. However, the small bowel follow-through can miss short skip lesions in Crohn's disease, as well as the aphthoid ulcers of early Crohn's disease. If a surgeon desires a full evaluation of disease extent and possible skip lesions before surgery in a patient with known Crohn's disease, enteroclysis is a better preoperative examination. If a patient has a normal-appearing terminal ileum during a small bowel follow-through but there is a strong clinical suspicion of Crohn's disease, a peroral pneumocolon can be obtained for air-contrast views of the terminal ileum. Ideally, this study should be performed after the patient has received a barium enema preparation to eliminate debris from the distal ileum and right side of the colon. A peroral pneumocolon or double-contrast barium enema with reflux of barium into the terminal ileum enables much better detection of mucosal nodularity and aphthoid ulcers (Fig. 37-30) than a conventional small bowel follow-through.

Enteroclysis may not visualize the terminal ileum any better than a small bowel follow-through (see Fig. 37-22). Over-distention of ileal loops in the pelvis during enteroclysis may cause so much overlap of loops that it is difficult to demonstrate the terminal ileum in isolation. The double-contrast effect of enteroclysis using methylcellulose is often lost before barium has reached the terminal ileum because of progressive mixing of barium and methylcellulose. An air-contrast enteroclysis may be performed, but a peroral pneumocolon or double-contrast barium enema is easier on the patient and will enable air-contrast images of the terminal ileum to be obtained in the 85% of patients in whom air or barium can be refluxed into the terminal ileum.

SMALL BOWEL OBSTRUCTION

As described in Chapter 46, the sun never sets on patients with suspected small bowel obstruction without these patients undergoing abdominal CT (unless they go directly to surgery). CT has a major advantage over barium studies in that it does not rely on barium reaching the site of obstruction but uses intraluminal fluid to outline the transition zone. CT also is a considerably shorter procedure than an antegrade barium study in patients with high-grade obstruction. A small bowel follow-through and enteroclysis are therefore discouraged in patients with high-grade small bowel obstruction shown by plain abdominal radiography or CT. Retrograde examination of the small bowel by barium enema (Fig. 37-31) or colostomy enema is the preferred examination in the setting of high-grade distal small bowel obstruction or if there is a question of whether the patient has an adynamic ileus, proximal colonic lesion, or distal small bowel obstruction. An antegrade study can be performed after decompression by a nasogastric tube or long tube (Kantor or Miller-Abbott tube; Fig. 37-32) or via a combination enteroclysis-decompression catheter.

Vomiting is more a symptom of gastroduodenal or proximal small bowel disease than of distal small bowel disease. In patients with vomiting and no evidence of plain radiographic or CT findings of distal small bowel obstruction, a single- or double-contrast upper GI series with evaluation of the proximal small bowel may be performed. Alternatively, if an upper endoscopy has cleared the stomach and proximal duodenum, enteroclysis or hypotonic duodenography extending into the first several small bowel loops may be considered.

ABDOMINAL PAIN

Unexplained abdominal pain can be evaluated by a small bowel follow-through or enteroclysis. The small bowel follow-through is superior to enteroclysis for evaluation of small bowel transit time and the motility component of motor disorders. In contrast, enteroclysis is superior for showing the structural

Figure 37-29 Multiple fistulas demonstrated on small bowel follow-through in a patient with Crohn's disease. An overhead radiograph obtained after barium reached the colon shows several tracks (*thick arrows*) coursing from the dilated distal ileum (*i*) to the ascending colon (*a*). One of these is a diseased terminal ileum and the other is an ileocolic fistula. Another fistula (*open arrow*) enters the medial wall of the ascending colon above the ileocecal valve. A thin, barium-etched fistula (*thin arrows*) courses from the ileum to the barium-filled urinary bladder (*b*). *r*, rectum.

Figure 37-30 Peroral pneumocolon in a patient with suspected Crohn's disease. **A.** Spot radiograph from small bowel follow-through shows an abnormal terminal ileum, manifested by sacculations (*arrows*) alternating with areas of narrowing. **B.** Spot image from peroral pneumocolon shows that most of the areas of narrowing are more distensible than shown in **A**. Several mesenteric border ulcers (*long arrows*) and sacculations (*short arrows*) characteristic of Crohn's disease are now visualized. The mucosa is focally nodular (*open arrow*). Compare and contrast the appearance of the mucosa in the terminal ileum with that in an adjacent loop of normal ileum (*n*).

Figure 37-31 Recurrent carcinoid tumor with small bowel obstruction on barium enema. The distal ileum is dilated, and small bowel folds are tethered (*open arrow*). In one loop, folds are bunched together (*arrowhead*) by the mesenteric desmoplastic process, and the opposite walls are sacculated (*large arrows*). Several short segments of narrowing (*short arrows*) are also seen. The ascending colon is identified (A).

components of motor disorders (e.g., diverticula in jejunoileal diverticulosis, sacculations or an increased number of small bowel folds in scleroderma). Enteroclysis is also superior for showing short lesions such as isolated adhesions (*Fig. 37-33*) or tumors that may account for abdominal pain.

Transient intussusceptions usually occur as normal variants or are associated with motor disorders. When a transient intussusception shown on CT is associated with signs of obstruction or tumor, the radiologist should perform enteroclysis because this technique is superior for excluding short lesions, such as tumors and adhesions, which may cause intussusception. However, most transient intussusceptions are not associated with signs of obstruction or tumor. In this scenario, it is unclear whether a small bowel follow-through is sufficient for excluding a structural abnormality. Clearly, enteroclysis will provide a more confident diagnosis of normality for ruling out tumor or an adhesion in this setting.

SUSPECTED PERFORATION

As noted, suspected perforation of the duodenum and proximal jejunum can be adequately evaluated with a water-soluble, small bowel follow-through. Diagnosis of perforation in the presence of dilated small intestine from obstruction or adynamic ileus is difficult, however, because water-soluble contrast agents provide inadequate density when diluted by intraluminal fluid. Water-soluble contrast agents are further diluted because of their hyperosmolar nature, which causes more fluid to be drawn into the small bowel lumen. In the presence of dilated distal small intestine, retrograde examination of the small bowel with water-soluble contrast agents is therefore preferable for excluding a

Figure 37-32 Complete small bowel obstruction demonstrated on enteroclysis after decompression of the small bowel by a Miller-Abbott tube. There is an abrupt, beaklike cutoff in the ileum (*long white arrow*) with complete small bowel obstruction caused by an adhesion. The proximal small intestine has been decompressed by a Miller-Abbott tube (the tip of the tube is denoted by a *short white arrow*) and is only mildly dilated. The mercury-filled bag (M) has flipped in a retrograde fashion. Note how the tube is seen as a filling defect (*black arrow*) in the barium column.

Figure 37-33 Adhesions and low-grade small bowel obstruction demonstrated on enteroclysis. This patient had intermittent abdominal pain and distention and a history of prior abdominal surgery. There is abrupt angulation (*black arrow*) of the ileum, with narrowing (*white arrow*) distal to the site of angulation. The folds in the transition zone are preserved, and the mucosa is smooth. The ileum (I) proximal to the adhesion is mildly dilated.

distal small bowel leak, particularly a leak at an ileocolic anastomosis. Water-soluble enteroclysis (see Fig. 37-24) should be performed after intestinal decompression in patients with suspected perforation of the mid- or distal small bowel.

MALABSORPTION

A classification and discussion of malabsorption is presented in Chapter 43. A small bowel follow-through is adequate for detecting large structural lesions that cause bacterial overgrowth (e.g., jejunoileal diverticulosis, Crohn's disease with obstruction). However, enteroclysis is the procedure of choice for showing malabsorptive disorders involving the mucosa and submucosa of the bowel (e.g., celiac disease [Fig. 37-34], Whipple's disease, amyloidosis). A strong argument can therefore be made for air-contrast enteroclysis in the setting of malabsorption because the mucosal surface of the jejunum, the most common site of disorders causing malabsorption, can be exquisitely shown. CT is also a helpful adjunct for diagnosing disorders primarily or secondarily involving lymph nodes.

UNEXPLAINED GASTROINTESTINAL BLEEDING

A small bowel follow-through is limited for detecting causes of small intestinal bleeding.^{39,43-48} Small tumors are easily missed.⁴⁵ In one study comparing expertly performed enteroclysis with non-expertly performed small bowel follow-through procedures, enteroclysis detected 90% of tumors diagnosed at surgery,

whereas small bowel follow-through detected only 33%.⁴⁵ It is therefore difficult to establish a confident diagnosis of normalcy on a small bowel follow-through. A combination of a small bowel follow-through (to exclude obstruction or stricture) and capsule endoscopy may be an acceptable alternative for evaluating patients with GI bleeding. However, capsule endoscopy also has its limitations. Because normal small bowel transit time varies from 30 to 120 minutes, the gastroenterologist or physician's assistant will spend an inordinate amount of time at a computer workstation evaluating the images. Capsule endoscopy also has limited ability to localize lesions. Finally, capsule endoscopy is not infallible, because a considerable portion of the intestine is not examined by the video capsule.

Methylcellulose-contrast enteroclysis is adequate for the demonstration of most small bowel tumors (see Fig. 37-7). However, it usually will not detect varices, arteriovenous malformations, or nonsteroidal anti-inflammatory drug (NSAID)-induced erosions or potassium chloride-induced erosions as well as capsule endoscopy. Air-contrast enteroclysis may allow diagnosis of subtle ulcerative lesions in the proximal small intestine with greater sensitivity than methylcellulose-contrast enteroclysis. Although I have not had great success with air-contrast enteroclysis in the pelvic ileum, this is the standard enteroclysis technique performed in Japan.

In summary, a small bowel follow-through is indicated only when assessing for large structural causes of GI bleeding (Fig. 37-35). This test is probably indicated only if there is low

Figure 37-34 Celiac disease demonstrated on enteroclysis. Spot image shows a decreased number of folds per inch in the jejunum.

Figure 37-35 Ileocecal lymphoma demonstrated on small bowel follow-through. Spot image of the ileocecal region shows marked lobulation and enlargement of the ileocecal valve (arrows), with spread of tumor into the medial wall of the cecum and ascending colon. The folds of the distal ileum also are marked enlargement and lobulated (arrowheads). This patient with mantle cell lymphoma presented with GI bleeding.

Figure 37-36 Gastrointestinal stromal tumor demonstrated on small bowel follow-through. A. Spot image shows a large, irregular, barium-filled cavity (U) on the mesenteric border of the mid-small bowel. Coarse, lobulated tumor nodules (arrows) are present adjacent to the cavity. **B.** Axial CT scan shows the bulk of the tumor (arrows) surrounding the cavity (u). The mucosal changes are not apparent. This patient presented with GI bleeding.

TABLE
37-2

Choice of Barium Studies for Evaluating Small Bowel in Various Clinical Settings

Clinical Scenario	Initial Study
Chronic diarrhea (excluding Crohn's disease)	Small bowel follow-through
Known Crohn's disease	
Acute abdominal pain	CT to exclude abscess
Anastomotic recurrence	Barium enema
Exclude skip lesion before surgery	Enteroclysis
Acute abdominal pain	CT (ultrasound if gynecologic disease suspected)
Chronic abdominal pain	Small bowel follow-through followed by enteroclysis if small bowel disease is still suspected
Small bowel obstruction	CT followed by barium enema as problem-solving tools for high-grade distal small bowel or proximal colonic obstruction
Low-grade obstruction	Small bowel follow-through or enteroclysis
Vomiting	Upper GI series with evaluation of proximal small bowel
Malabsorption	Enteroclysis (consider air-contrast)
Unexplained GI bleeding	Small bowel follow-through, capsule endoscopy
	Methylcellulose enteroclysis
	Air-contrast enteroclysis if NSAID erosions must be excluded
	CT angiography—role to be determined
Suspected hematogenous metastases	Enteroclysis
Suspected perforation	CT can suggest presence of perforation; suboptimal for evaluating site and cause of perforation
Upper GI tract	Water-soluble contrast upper GI series
Bypassed duodenum	HIDA scan or injection of water-soluble contrast agent into indwelling duodenal-biliary tube
Proximal jejunum	Small bowel follow-through with water-soluble contrast
Mid-small bowel	Water-soluble contrast enema or water-soluble contrast enteroclysis
Distal small bowel, ileocolic anastomosis	Water-soluble contrast enema

HIDA, Hepato-iminodiacetic acid; NSAID, nonsteroidal anti-inflammatory drug.

suspicion of an abnormality, if a large lesion such as lymphoma, GI stromal tumor (Fig. 37-36), ischemia, or hematoma is suspected, or if capsule endoscopy is planned as a follow-up.

Air-contrast enteroclysis is indicated when looking for subtle erosions in patients taking NSAIDs. Methylcellulose-contrast enteroclysis and air-contrast enteroclysis are satisfactory when searching for subtle lesions or small tumors. In patients with known malignant tumors, enteroclysis will permit a more confident diagnosis of normalcy or of metastatic disease than will a small bowel follow-through.

The role of CT or MR angiography for bleeding tumors has yet to be established. CT and MR enterography are

inferior to enteroclysis because they do not assess en face mucosal detail and they have lower resolution than enteroclysis. As a result, barium enteroclysis should be superior to CT or MR enteroclysis for the diagnosis of Crohn's disease, diseases causing malabsorption, or primary tumors. I believe that if a patient is to undergo intubation, a barium enteroclysis study should be performed (rather than CT or MR enteroclysis), except perhaps when searching for a cause of GI bleeding.

A summary of the choice of examinations for evaluating the small bowel in various clinical settings is presented in Table 37-2.

CHAPTER OUTLINE

Computed Tomography Enterography: How It Differs From Routine Abdominal Computed Tomography

Indications

Technique

Interpretation of Computed Tomography Enterography Images

Suspected Crohn's Disease

Gastrointestinal Bleeding

Low-Grade Obstruction

Radiation Dose and Computed Tomography Enterography

Integration with Other Tests

Computed Tomography Enterography: How It Differs From Routine Abdominal Computed Tomography

Computed tomography enterography (CTE) reflects individualization of the abdominal pelvic CT technique for patients with small bowel disorders. CTE provides visualization of the small bowel lumen, wall, and perienteric tissues by distending the small bowel with large volumes of oral contrast and obtaining multiplanar, high-resolution images of the bowel during appropriate phase(s) of enhancement. It differs from routine abdominal pelvic CT in the amount and type of oral contrast given to the patient prior to scanning, timing of image acquisition with respect to the intravenous (IV) contrast bolus, routine reconstruction of thin multiplanar images, and other factors related to patient-specific indications (e.g., Crohn's disease or obscure gastrointestinal [GI] bleeding). CT acquisition for CT enteroclysis is similar, but the luminal small bowel distention is achieved by infusion of enteric contrast via a nasojejunum tube.

Indications

CTE is performed in patients with known or suspected Crohn's disease, patients with obscure GI bleeding, diarrhea of unknown cause (often in association with imaging of the pancreas), and in patients with abdominal pain of unknown cause in an outpatient setting. Multiphase CTE is often used as a complementary technique with capsule endoscopy in patients with obscure GI bleeding, and its complementarity with other tests is reviewed later in this chapter. CTE may also be used to evaluate for the presence and cause of low-grade obstruction (when an enteroclysis cannot be performed), and to examine for findings or

complications of other small bowel disorders (e.g., small bowel diverticulosis, celiac disease, polyposis syndromes).

Technique

The CTE technique is adapted to the indication for the examination. Table 38-1 describes common variations of CTE technique, linking them to clinical indications. All types of CTE require the ingestion of large amounts of oral contrast and adaptation of the CT x-ray tube potential and tube current to adjust for patient size and diagnostic task to minimize radiation dose appropriately, yet provide an accurate diagnosis.¹

For CTE, 1300 to 2000 mL of oral contrast is typically administered to the patient over an hour in divided increments (e.g., 450 mL at 60, 45, and 15 minutes prior to the examination).²⁻⁵ Contrast agents are generally divided into neutral enteric agents that demonstrate CT number attenuation similar to that of water and positive enteric contrast agents containing barium or iodine, which have CT numbers much greater than those of enhancing structures. Neutral agents are preferred for most small bowel indications because they allow greater conspicuity of many small bowel pathologies, such as segmental inflammation or masses, which usually are hyperenhancing compared with the adjacent small bowel wall. Positive agents are useful when the suspected pathology is known to be an intraluminal filling defect (e.g., polyposis syndromes), serosal metastases are suspected, or IV iodinated dye is contraindicated. Although a variety of neutral enteric contrast agents are available, many centers use commercially available products, which often contain sorbitol, which retards absorption of water across the small bowel wall, improves small bowel distention compared with water alone, and provides an expanded time window during which small bowel imaging can be achieved with a high degree of reproducibility.³ Alternatively, locust bean gum or polyethylene glycol may also be used.^{2,6} If patients have difficulty with oral ingestion of these neutral agents, they can complete ingestion of the recommended volume with water. Patients need to be informed that enteric agents using sorbitol or polyethylene glycol may cause loose bowel movements as the agent is expelled shortly after the test. Because of the requirement for the ingestion of large volumes, CTE using non-water agents is an outpatient procedure, and radiologists and referring clinicians should consider alternatives for hospitalized patients (for whom routine abdominal-pelvic CT or CTE with water may be preferred). Also, approximately 30% of jejunal loops will be collapsed using the peroral CTE technique⁷; therefore, so in the presence of known or suspected jejunal pathology, CT enteroclysis or magnetic resonance (MR) enterography, in which the jejunum is imaged repeatedly with different pulse sequences, may be preferred.

IV contrast is typically delivered at a rate of 3 to 5 mL/s, with imaging during the enteric or portal phase of enhancement. The enteric phase of enhancement refers to imaging during

TABLE
38-1

Common Types of Computed Tomography Enterography Examinations by Patient Indication

Indication	Phase(s) of Enhancement	Dose Level	Comments
R/O small bowel disease	Enteric or portal	Routine abdominopelvic CT	Neutral oral contrast, high resolution*
R/O or FU Crohn's disease	Enteric or portal	Less than for routine abdominopelvic CT	Neutral oral contrast, high resolution*
Active GI bleed	Arterial and portal or delayed	Routine abdominopelvic CT	Neutral oral contrast, high resolution*
Obscure GI bleed	Arterial, enteric and delayed	More than for routine abdominopelvic CT (because of more than one phase of enhancement)	Neutral oral contrast, high resolution*
Polyposis syndrome	Noncontrast	Less than for routine abdominopelvic CT	Enteroclysis preferred, positive oral contrast, high resolution
Low-grade obstruction	Enteric or portal	Routine abdominopelvic CT	Enteroclysis preferred, neutral oral contrast, high resolution

*Axial slice thickness is ≤ 3 mm, with routine coronal \pm sagittal multiplanar reconstructions or interactive 3D viewing of volumetric CT data at a computer workstation.

CT, computed tomography; FU, follow-up; GI, gastrointestinal; R/O, rule out.

peak enhancement of the small bowel wall, which is generally regarded as 50 seconds after the initiation of IV contrast material.⁸ The enteric phase demonstrates findings of Crohn's disease, hyperenhancing polyps, and most small bowel vascular lesions. The timing of the enteric phase is similar to that of the pancreatic phase because the superior mesenteric and portal veins are opacified with IV contrast media and the hepatic veins have not yet filled with contrast; thus, synchronous evaluation of the pancreas can often be performed with a single acquisition. In the hepatic or portal phase of enhancement, hepatic veins are filled with contrast; this may be a more appropriate phase of enhancement if correlative imaging of the liver is also needed. For the most common indication of imaging Crohn's disease, active Crohn's disease is adequately demonstrated in the enteric and portal phases.⁹

Because one of the goals of CTE is to display small fistulas and intramural or intraluminal masses, high-resolution CT imaging is required, with the axial slice thickness generally reconstructed on the order of 3 mm or less. Multiplanar coronal reformatted images are required, and sagittal reformatted images are also generally obtained to aid in the evaluation of suspected small bowel segments and the mesenteric vasculature. The pitch or CT scanner table speed is adjusted so that the abdomen and pelvis can be imaged within a single breath-hold (i.e., 6 to 15 seconds). For most clinical indications (e.g., to rule out small bowel disease, evaluate Crohn's disease), only a single phase of contrast enhancement is required.⁹

Irrespective of the indication, the CTE acquisition technique should be adapted to patient size and diagnostic goal.^{1,10} One of the best radiation dose-saving techniques is for the radiologist to limit the number of phases acquired to those that are necessary for the suspected diagnosis. Multiple phases of enhancement are reserved for the investigation of obscure GI bleeding¹¹ or situations in which multiphasic imaging of solid organs is required. Tube current adaptation can be carried out through the use of technique charts or automatic exposure control.^{12,13} The routine use of automatic exposure control will lower radiation dose by approximately 30% in large CT practices.¹² Additionally, tube energy selection (kV) can be performed using technique charts or vendor-supplied kV selection programs, which take into account patient size, iodine contrast-to-noise ratio (CNR), and CT system limitations.¹⁴ Selection of kV and technique charts generally reduce radiation dose by an

additional 20% to 30%. One of the advantages of lower kV is that it not only reduces radiation dose, but increases the iodine signal and iodine-related CNR, which can be used to increase the conspicuity of hyperenhancing bowel segments and masses or lower the radiation dose.

The dose level chosen for different types of enterography examinations depends on the image contrast between the suspected small bowel pathology and normal, enhancing bowel wall, as well as other pathology, which may be suspected in the solid organs (see Table 38-1). In Crohn's disease, the diagnostic task requires differentiating relatively large differences in CT number between normal and hyperenhancing bowel segments, so routine abdominal pelvic CT dose levels can be lowered by 30% to 50% without sacrificing diagnostic performance.^{13,15,16} Similarly, if using positive enteric contrast to evaluate for filling defects such as polyps in polyposis syndromes, the CT number differences between the suspected pathology and adjacent bright lumen are large, and the radiation dose can be substantially reduced (analogous to CT colonography). In contrast, CTE performed to evaluate synchronously for pancreatic or small bowel masses or hepatic metastases will require routine abdominal pelvic dose level settings so that important low-contrast structures and masses can be visualized adequately.

The lower radiation dose levels frequently used in CTE, along with the thinner slices, often result in noisier images, which can be accurately interpreted without diagnostic compromise in the setting of Crohn's disease.^{13,15,17} A variety of CT image noise reduction methods can be used (e.g., iterative reconstruction) to improve the image quality of the lower dose CTE images so that they resemble those obtained with a routine dose.¹⁸ CT noise reduction is especially useful when reducing radiation dose with low-kV techniques to improve disease conspicuity and compensate for the increased image noise associated with low-kV imaging.^{1,19}

Interpretation of Computed Tomography Enterography Images

Routine CT enterography performed for general indications of Crohn's disease requires only the review of axial and coronal images, although interactive viewing with a volume viewer or

in other planes is often helpful. Similar to fluoroscopy, a systematic approach to view the bowel is required to maximize disease detection. Because Crohn's disease, GI bleeding, and small bowel tumor exclusion are frequent indications for CTE, CT findings in these entities will first be considered, with emphasis on the differential diagnosis. Appropriate diagnosis relies on combining knowledge of the intraluminal morphology seen at fluoroscopy with the mural and intraluminal enhancement seen at cross-sectional imaging.

Normal small bowel findings at CTE are similar to those observed fluoroscopically. The jejunal caliber is slightly larger than the ileum, and the jejunal valvulae conniventes are slightly thicker and more closely spaced than in the ileum.²⁰ Approximately 30% of jejunal folds will be collapsed and should not be confused with small bowel masses.⁷ In the enteric phase of enhancement, the jejunum enhances to a significantly greater degree than the ileum, with the attenuation difference normalizing in later phases²¹ (Fig. 38-1).

SUSPECTED CROHN'S DISEASE

CTE images in patients with known or suspected Crohn's disease should be scrutinized for CT findings of mural inflammation anywhere along the GI tract, penetrating disease (e.g., sinus tracts, fistulas, phlegmon, and abscesses), bowel obstruction, and inflammatory bowel disease (IBD)-related extraenteric findings, including mesenteric venous thromboses, sacroiliitis, and primary sclerosing cholangitis. Chapters 40 and 54 describe the imaging features of Crohn's disease in greater detail.

CT findings of mural inflammation include segmental mural hyperenhancement, mural thickening, mural stratification, abnormal mural or perienteric fat, and the comb sign.⁵ Mural hyperenhancement refers to segmental attenuation (or enhancement) greater than that of adjacent small bowel loops.²² Although not specific, it is generally considered to be the most sensitive findings for Crohn's disease-related inflammation,¹⁶ and it is highly correlated with endoscopic and histologic findings of inflammation.²² Because the jejunum

enhances more avidly than the ileum, comparison to only nearby loops is important in this evaluation. Jejunal hyperenhancement associated with jejunal Crohn's disease is often more difficult for radiologists to appreciate because of the prominence of the valvulae conniventes, or jejunal folds (Fig. 38-2). Other imaging features such as penetrating ulcers, mural thickening, and disruption of the fold pattern are often seen in jejunal Crohn's disease, which frequently involves a longer length and multiple segments compared with ileal Crohn's disease.

A wide variety of diseases can also cause mural hyperenhancement; however, patchy and asymmetric hyperenhancement or continuous hyperenhancement along the mesenteric border are pathognomonic for Crohn's disease (Video 38-1; Table 38-2). Contraction of small bowel loops can cause increased attenuation of a small bowel loop,²¹ but is usually readily distinguished by smooth tapering of the adjacent distended segments on either end. Infection, backwash ileitis, angioedema (often from angiotensin-converting enzyme [ACE] inhibitors), vasculitis, and bowel ischemia can all cause segmental hyperenhancement of bowel loops. However, these entities are not usually associated with asymmetric enhancement or penetrating complications. When faced with equivocal hyperenhancement, comparing two nearby distended bowel loops and taking into account secondary signs of Crohn's disease (e.g., mural stratification, perienteric edema, and the comb sign) are often helpful. Radiation enteritis can also produce narrowed and hyperenhancing bowel loops, but it is easily distinguished from Crohn's disease because of the history of radiation and symmetric hyperenhancement.²³

An additional video for this topic is available online.

Mural thickening greater than 3 mm is also considered abnormal in small bowel loops in which the lumen is distended. Collapsed bowel loops, especially in the jejunum, can sometimes be mistaken for small bowel wall thickening because of the valvulae conniventes, which can become confluent when the

Figure 38-1 Normal CTE images. A, B. Coronal images demonstrate a normal small bowel appearance with CTE performed in the enteric phase in a 46-year-old man with negative capsule endoscopy. Note the increased number of folds and increased enhancement in the jejunum, in addition to the collapse of several jejunal loops, all of which are normal findings.

Figure 38-2 CTE images of inflammatory and infectious jejunal Crohn's disease. **A, B.** Jejunal Crohn's disease is manifested by disruption of the normal fold pattern, asymmetric involvement (**A**, arrowhead), segmental hyperenhancement compared with normal jejunal loops (**B**, inset and arrows), and mural stratification (**A, B**, arrowheads). **C.** Celiac sprue demonstrates a diffuse loss of jejunal folds. **D.** Neutropenic enterocolitis (arrows) appears similar to Crohn's disease but involves long bowel segments and symmetric mural stratification; it is seen in immunocompromised patients.

TABLE 38-2

Differential Diagnosis of Segmental Small Bowel Mural Hyperenhancement

Disease Entity	Comments	Differential Imaging Features
Crohn's disease	Jejunal involvement frequently overlooked	Asymmetric, patchy or mesenteric border hyperenhancement; multifocality; perianal disease or other penetrating complications
Backwash ileitis		Symmetric involvement; continuous with pancolonic involvement, patulous ileocecal valve
Angioedema	Often associated with abdominal pain and use of ACE inhibitors	Symmetric involvement, dilated loop, ascites
Contraction, peristalsis	Delayed images often help	Smooth tapering on proximal and distal ends; compare with other phases of enhancement
Radiation enteritis	History of pelvic radiation	Long-segment hyperenhancement without asymmetry
NSAID enteropathy	History of NSAID ingestion	Focal 1- to 2-cm lesion, often multiple, with intervening normal-appearing bowel
Ischemia	Patient often older or had recent cardiac event	Symmetric involvement; concurrent closed loop obstruction, venous or arterial occlusion or thrombosis
Infection or neutropenic enteritis	Clinical history often suggestive	Symmetric involvement
Vasculitis		Symmetric involvement; vessel and solid organ involvement

lumen is collapsed. Similar to hyperenhancement, mural thickening in Crohn's disease is frequently asymmetric and located along the mesenteric border. Focal or segmental wall thickening can be seen in hemorrhage and intestinal edema, as well as the spectrum of entities causing mural enhancement (see earlier).

Other imaging findings can be seen in Crohn's disease-related enteric inflammation. Mural stratification (also called the target sign) refers to a laminated appearance (two or three layers) to the bowel wall and is often seen in IBD (Crohn's disease, ulcerative colitis) and other benign small bowel

diseases.^{4,23,24} It is usually related to inflammation (Crohn's disease, nonsteroidal anti-inflammatory drug (NSAID) enteropathy), infection, or a vascular cause (e.g., ischemia, hemorrhage, vasculitis, radiation enteritis). Fibrofatty proliferation of the mesentery is a pathognomonic finding in Crohn's disease.⁴ Similar to mesenteric border linear ulcers seen at small bowel fluoroscopy, fibrofatty proliferation appears on the CT examination as a large amount of fat along the mesenteric border of small bowel loops or circumferentially about the rectum. The comb sign is not pathognomonic but is frequently seen in IBD; it refers to engorged vasa recta,²⁵ which enter the bowel at angles and become enlarged in active inflammation.

Penetrating Crohn's complications such as fistulas, sinus tracts, phlegmons, and abscesses frequently are seen in approximately 25% of Crohn's patients, and their detection frequently leads to changes in medical management or radiologic or surgical intervention.^{26,27} Fistulas appear as extraenteric tracts on CTE, generally arise from inflamed small bowel loops, and may be clinically unsuspected in up to 50% of cases.²⁸ Crohn's fistulas often cause tethering of affected small bowel loops, and asterisk-shaped fistulas complexes are often seen between distal ileal loops, sigmoid or ascending colon, and the bladder (Fig. 38-3). Fistulas are named by the structures to which they connect (e.g., enteroenteric, enterocutaneous, enterovesical, perianal). Fistulas can arise from other causes, usually as a result of surgery, infection, or pancreatitis. Rarely, pelvic infection with actinomycosis can mimic fistulizing Crohn's disease with

bowel wall thickening, with diffuse inflammatory changes in the mesentery, fistulas, (including perianal fistulas), or masslike phlegmonous change, often in women with an IUD.²⁹

Neoplasms can be confused with small bowel Crohn's disease. Primary GI lymphoma can cause asymmetric segmental wall thickening, but it is generally distinguished by lack of hyperenhancing bowel loops. Carcinoid small bowel disease will occasionally be mistaken for Crohn's disease. The clue to this diagnosis is the multifocality of the masses and characteristic appearance of the mesenteric metastasis. The imaging differentiation of these entities from Crohn's disease can sometimes be difficult and require biopsy because both tumors can arise in the setting of chronic Crohn's inflammation in addition to adenocarcinoma.

GASTROINTESTINAL BLEEDING

CTE for gastrointestinal bleeding is generally performed for obscure GI bleeding, with endoscopy, CT angiography, or abdominal and pelvic CT performed in the acute setting. CTE for obscure GI bleeding is performed after upper and lower endoscopy and is included in the 2011 American Society for Gastrointestinal Endoscopy (ASGE) practice guidelines for overt and obscure GI bleeding.³⁰ Obscure GI bleeding is recurrent or persistent bleeding with no source found at initial upper and lower endoscopy. Overt obscure GI bleeding means that bleeding is visible as melena, hematemesis, or hematochezia,

Figure 38-3 CTE images of Crohn's disease. Crohn's fistulas often cause tethering of affected small bowel loops, and asterisk-shaped fistulas complexes are often seen between the affected bowel loops. **A.** Complex enteroenteric fistula involving multiple ileal loops (arrows). **B.** Ileosigmoid fistula (arrow). **A to C.** Fistulas generally arise from inflamed bowel loops (arrowheads) and may also communicate to the skin or other organs. **C.** Ileovesical fistula (arrow). **D, E.** Perianal fistulas (arrows) are enhancing extraenteric tracts that usually do not contain air or fluid, but are distinguishable from the anal sphincters by their hyperenhancement.

whereas occult, obscure GI bleeding occurs in those with iron deficiency anemia.³¹ Common causes of GI bleeding in younger patients include small bowel tumors, Meckel's diverticula, Crohn's or celiac disease, Dieulafoy lesions, and varices; angioectasias, NSAID enteropathy, and celiac disease are more common in older individuals.³¹

Interpretation of multiphasic CTE in obscure GI bleeding is challenging and requires a systematic approach because of the variety of potential bleeding sources. The role of the radiologist is to identify any active bleeding in addition to any underlying causes, such as a tumor or vascular lesion. An initial search is performed of images obtained during the arterial phase of enhancement for high-attenuation structures that may indicate intraluminal debris, active bleeding, neoplasm, or vascular lesions, with findings correlated on the subsequent phase of enhancement to distinguish small bowel lesions from intraluminal debris and bleeding. Debris often possesses sharp edges and appears unchanged over multiple phases. A progressive accumulation of intraluminal contrast signals active bleeding (Fig. 38-4). The morphology of the small bowel lesions (e.g., intraluminal filling defects or focal regions of bowel thickening) will aid in narrowing of the differential diagnosis. Intraluminal filling defects that are not debris generally represent a neoplasm, arise from the bowel wall, and will change in enhancement over time. Focal regions of bowel thickening, such as Crohn's disease, lymphoma, and metastases, will also have an enhancement that evolves progressively.

Small bowel tumors are frequently identified at multiphase CTE in patients with obscure GI bleeding. Tumors in these patients tend to be smaller and at an earlier stage than symptomatic patients. Several studies have suggested that small bowel neoplasms may be more readily identified at CTE than capsule endoscopy because of their exoenteric or submucosal origin.^{11,32,33} Carcinoid (neuroendocrine) tumors are generally hyperenhancing tumors and may appear as an enhancing polyp, often with a shoulder-like morphology, with slight puckering or retraction along the serosal surface, or as multifocal enhancing tumors over a distance of 20 to 30 cm³⁴ (Fig. 38-5). The involvement of mesenteric vessels by tumors can simulate the segmental wall thickening seen in Crohn's disease, but will also cause retraction of the affected bowel loops. In obscure GI bleeding, focal small bowel lesions with classic mesenteric metastases with soft tissue, radiating strands of desmoplasia adjacent to the primary tumor, or liver metastases are infrequently seen.³⁴

GI stromal tumors are known to hemorrhage and ulcerate frequently and are generally hyperenhancing, but may be isoenhancing. They may appear as round or intraluminal filling defects, but often have an exoenteric component.³⁵ Small bowel lymphomas demonstrate an appearance similar to that seen on routine abdominal CT (isointense enhancement, adjacent lymphadenopathy with or without aneurysmal ulceration), but are frequently smaller. Melanoma metastases are often seen as intramural lesions because of their hematogenous spread;

Figure 38-4 Two patients with active jejunal bleeding. **A to C.** These images demonstrate a jejunal angioectasia as displayed during arterial, enteric, and delayed phases, respectively (arrows). **D.** An image at a slightly inferior level shows layering of extravasated contrast in the distal jejunal lumen (arrowhead). **E, F.** Images in another patient poorly demonstrate the patient's jejunal vascular malformation (not shown), but indicate active jejunal bleeding in the enteric and delayed phases, respectively, with progressive accumulation of contrast within the jejunal lumen (arrows).

Figure 38-5 Neuroendocrine tumors demonstrated by CTE.

A. Small bowel carcinoid (neuroendocrine) tumors (arrowhead) can be seen as hyperenhancing polyps or mural masses, which are nonspecific in appearance. **B.** However, flat or sessile polyps with luminal shouldering (arrowheads) with retraction along the serosal surface (arrow) are characteristic for small bowel neuroendocrine tumors. **C.** Ileal carcinoids are often multiple (arrow). **D.** The tumors cause narrowing of the lumen (arrow).

however, in this clinical setting, they have a nonspecific appearance and are frequently not hypervascular.

Vascular lesions are often detected at capsule endoscopy and are increasingly being detected with multiphase CTE (Fig. 38-6). Huprich and colleagues have proposed a classification for vascular lesions at multiphase enterography that is analogous to the endoscopic classification of vascular lesions.^{36,37} They have classified vascular lesions at enterography into angiodysplasias, arterial lesions, and venous lesions. Angioectasias are the most common vascular small bowel lesions and are thin, tortuous veins that lack an internal elastic layer and possess arterial-venous communication. They are frequently multifocal and seen in older individuals. At CTE, they are rounded structures that are generally best seen in the enteric phase using multiplanar images or 3D workstations, with washout on delayed-phase images. In older individuals, it is common to see prominent jejunal veins, so identification of round morphology or active bleeding is imperative prior to referral to balloon endoscopy for ablation. Arterial lesions include Dieulafoy lesions, arteriovenous fistulas, and arteriovenous malformations. A Dieulafoy lesion is an artery in the submucosa that does not undergo normal branching and bleeds through a small mucosal defect. It manifests as an arterially enhancing lesion, often with active bleeding and extravasation of IV contrast into the bowel lumen; it is not associated with mucosal pathology. Because arterial lesions can be intramural,

arteriovenous malformations (AVMs) may be missed at prior colonoscopy and are not infrequently seen in the cecum and rectum. These lesions are often heralded by the presence of a dilated right ileocolic or superior hemorrhoidal vein in the arterial phase, whereas AVMs in the small bowel wall will also possess large draining veins.³⁸ Venous lesions include small bowel varices (congenital or caused by chronic mesenteric vein thrombosis in Crohn's disease), venous hemangiomas, and other venous lesions.

Meckel's diverticula are also a commonly identified source of GI bleeding, particularly in young patients, may have an internal ulcer, gastric mucosa, or tumor, and may intussuscept, with a classic appearance of fat within the intussusceptum surrounded by a collar of soft tissue.³⁹ NSAID enteropathy is a source of GI bleeding in older patients and is seen as a short segment of circumferential narrowing or luminal diaphragm, often causing a partial obstruction or capsule retention. The diaphragms are often multifocal and may demonstrate focal hyperenhancement.

LOW-GRADE OBSTRUCTION

Patients with high-grade small bowel obstruction present symptomatically to the emergency room and generally undergo routine abdominal CT, which can detect findings leading to surgical management.⁴⁰ CT and MR enteroclysis are more

Figure 38-6 CTE images of gastrointestinal vascular lesions. Vascular lesions can be classified as angioectasias, arterial lesions, and venous lesions (usually varices). **A.** Angioectasias (bracket) occur in older individuals, are most prominent in the enteric phase, and are distinguished from prominent penetrating veins by a lobulated or rounded shape, best seen on multiplanar or 3D reformations. **B.** Dieulafoy lesions are one type of arterial lesions and exhibit bright arterial enhancement (arrow), often with extravasation of IV contrast into the small bowel lumen (**C**, arrow), and can be treated endoscopically, as in this case. Venous lesions can be congenital or acquired. **D.** Crohn's disease patients often have chronic occlusion of the proximal superior mesenteric vein (arrow) or mesenteric venous branches, with collateral flow forming varices (**E**, **F**, arrows) over time.

sensitive for low-grade small bowel obstruction compared with CTE, but require nasojejunal intubation.^{41,42} CTE is often performed when the patient is unwilling to undergo enteroclysis or as a general imaging test to exclude small bowel pathology. The criteria for partial obstruction are identical to those for routine CT (zone of transition from dilated to decompressed bowel [see Chapter 46]); frequently seen causes include adhesions, tumors, Crohn's disease, hernia, radiation enteritis, intussuscepting Meckel's diverticulum, and diaphragm disease.

Patients with structuring Crohn's disease represent an important subpopulation of patients with partial obstruction at enterography. Approximately 20% of asymptomatic patients with strictures and partial small bowel obstruction at enterography will not have any symptoms.^{6,29} The term *strictures* is reserved for narrowed small bowel segments that cause proximal dilation and partial small bowel obstruction. Crohn's strictures generally have inflammatory and fibrotic components, with decreasing hyperenhancement and proximal dilation

correlating with the increased levels of fibrosis.⁴³ CTE is highly accurate for the detection of Crohn's strictures,⁴⁴ and detection of multifocal strictures can be especially important for guiding surgical management, such as stricturoplasty.⁴⁵

Radiation Dose and Computed Tomography Enterography

An understanding of anticipated benefits and risks is needed to inform patients and clinicians about the medical justification for a CTE examination.^{46,47} In terms of benefit, one large prospective study of over 250 patients with known or suspected Crohn's disease found that approximately 50% of patients with known Crohn's disease and 50% of patients with suspected Crohn's disease had management decisions changed as a result of CTE findings.²⁷ In patients with Crohn's disease, small bowel disease was excluded in approximately 12%, medication changes

were made in another 15%, and anticipated surgical management was altered in approximately 7%.²⁷ In another study of 152 IBD patients presenting to the emergency room of a tertiary care hospital, CTE changed management in 81% and 69% of Crohn's and ulcerative colitis patients, respectively, with urgent non-IBD diagnoses identified in 13% and 28% of patients, respectively.⁴⁸ In another study of approximately 150 Crohn's patients, about 50% of Crohn's patients with a normal-appearing ileum on ileoscopy had other objective evidence of mural or proximal small bowel inflammation.⁴⁹ Also, penetrating complications, which often prompt medical or surgical management, are unsuspected in up to 50% of Crohn's patients with fistulas or abscesses.²⁸ In obscure GI bleeding, the benefit of CTE is that it may detect small bowel tumors, which are difficult to find using optical methods alone. An additional benefit is that CTE can be performed and interpreted immediately on presentation in the case of overt, obscure GI bleeding, whereas capsule endoscopy requires 1 day to acquire and interpret data.

Nevertheless, Crohn's disease patients have higher cumulative radiation doses,⁵⁰ and an increased dose may be harmful for pediatric patients, particularly young females.⁵¹ The National Academies of Sciences BEIR VII report stated that "at statistical doses of 100 mSv or less, statistical limitations make it difficult to evaluate cancers in humans," but they concluded that "...the preponderance of information indicates that there will be some risk, even at low doses, although the risk is small."⁵² The radiation dose imparted by a single CTE examination is over an order of magnitude smaller than that cited in the BEIR VII report, and state of the art dose reduction techniques often result in examinations performed at dose levels similar to annual background radiation levels. Because of these concerns, however, MR enterography may be a more appropriate test in young individuals, especially those undergoing repeated outpatient examinations.⁵³ Both radiology and gastroenterology societies have considered the benefits and risks of CTE and recommend it as an appropriate test in the correct clinical setting.^{30,54}

Integration with Other Tests

Ileocolonoscopy is frequently performed synchronously with CTE because the two tests are considered complementary. Optical colonoscopy can detect and stage colonic inflammation better compared with CTE,⁵⁵ and it can also detect colonic neoplasia and perform surveillance biopsies for risk assessment. Enterography, on the other hand, can identify mural

and proximal disease in the ileum, particularly in the setting of terminal ileum skipping.⁴⁹ In the setting of obscure GI bleeding, all patients should undergo upper and lower endoscopy to detect treatable causes of GI bleeding originating from esophageal, gastric, duodenal, and colonic sources prior to small bowel imaging.

Capsule endoscopy is a very sensitive tool for mucosal inflammation in Crohn's disease but the capsule can be retained, necessitating endoscopic or surgical removal in patients with strictures. This may be a particularly significant problem in Crohn's disease, in which asymptomatic strictures may be present. Conversely, one of the limitations of CTE is the limited visualization of jejunal loops, and capsule endoscopy is likely to be complementary with CTE in detecting jejunal disease and early mucosal disease in the ileum.^{6,56} Capsule endoscopy is a first-line test in obscure GI bleeding after consideration has been given to repeat upper and lower endoscopy, and it provides complementary information compared with CTE.³⁰ Balloon-assisted endoscopy is used in many centers to investigate the cause of obscure overt GI bleeding and can be used to biopsy or treat small bowel lesions detected by capsule endoscopy or CTE.

MR enterography is also routinely used to detect small bowel Crohn's disease. Several prospective studies have shown that the performance of CTE and MR enterography is similar for identifying mural inflammation in small numbers of patients.^{57,58} CTE is easier to accomplish in a practice setting and may be less prone to interobserver variability.⁵⁹ MR enterography is often preferred for younger patients because of the lack of ionizing radiation and necessity for CT imaging in acute flares.⁵³ CTE may be especially useful when MR expertise and experience are not available, there is a clinical concern for sepsis, the patient is having her or his first CTE examination, or suspected, complex intra-abdominal penetrating disease is present, which may prompt further surgical or interventional therapy, or in older patients. In these situations, the clinical benefit of CTE will far outweigh potential risks. MR enterography, given limited resources, may be more useful in asymptomatic patients, when obstruction is suspected, or when patients are younger or have known perianal disease.

Fluoroscopic small bowel examination is useful, particularly in patients with colonic resections or resections of the ileocecal valve, so the functional importance of narrowed and dilated segments can be ascertained. Moreover, fluoroscopic examination also provides a single view of complex small bowel disease in the presence of prior surgical changes.

CHAPTER OUTLINE

Historical Background

Clinical Indications and Comparison With Other Imaging Methods

Small Bowel Crohn's Disease

Small Bowel Neoplasms

Small Bowel Obstruction

Miscellaneous Indications

Technical Pitfalls and Limitations

Comments

Summary

"As the number of imaging examinations and radiologic procedures continues to rise, so do radiologists' opportunities to improve their roles as consultants and clinical team members."¹ The mesenteric small intestine is the most challenging segment of the gastrointestinal (GI) tract to examine. It is the longest segment of the alimentary tube and has the widest mucosal surface, yet the incidence of disease is low and the clinical presentations are mimicked by diseases of adjacent visceral organs, with a higher incidence of abnormalities. The significant role of imaging, therefore, is to exclude small bowel (SB) disease reliably or diagnose early, small, or localized disease with confidence.²⁻¹⁷

Methods of imaging that do not distend the SB lumen have historically been shown not to allow reliable exclusion of SB disease or early demonstration of small or early mucosal or submucosal abnormalities. In addition, these examinations do not give the radiologist and clinician the confidence to exclude small neoplasms and low-grade SB occlusion (SBO) or depict early mucosal SB Crohn's disease (aphthae) or nonsteroidal anti-inflammatory drug (NSAID) enteropathy. SB imaging reports are therefore not infrequently equivocal or noninformative, and repeated imaging examinations or performance of more expensive and invasive endoscopic methods are done before a definitive diagnosis or confident exclusion of SB disease is made.

The investigation of SB diseases requires methods of examination that have a high negative predictive value and high sensitivity. Intubation infusion examinations (enteroclysis and its modifications) have been shown to overcome most of the inherent limitations of conventional examinations (peroral ingested or nonenteral volume-challenged) but have inherent limitations.¹⁸ Decades of experience have shown that only examinations that distend the lumen and coat the mucosa fulfill these roles.^{2-17,19} Several of these reports were not generated from well-controlled clinical trials; many are experience-based. The enteroclysis technique and its modifications have remained the most accurate methods that reliably exclude SB abnormalities and allow early diagnosis of disease.

Progress in imaging of the SB during the past few decades has largely occurred because of refinements in the application of various modalities. These include orally ingested conventional abdominal and pelvic computed tomography (CT) or magnetic resonance imaging (MRI) with intravenous (IV) contrast (CT enterography and MR enterography), conventional barium enteroclysis methods (computed tomography enteroclysis [CTE] and magnetic resonance enteroclysis [MRE]), and technical refinements in performing double-contrast (DC) barium enteroclysis.^{7,20-82}

Some updates on how to perform CTE, its modifications, and DC barium enteroclysis, as well as its clinical applications, have been recently described but are beyond the scope of this chapter. Interested readers are referred to these articles.^{51,83-85}

This chapter presents an update of the current role of CTE modifications in the diagnosis and management of SB diseases from evidence- and experience-based analyses. We examine why enteral volume-challenged examinations, despite their reported higher accuracy and reliability in ruling out SB disease, are infrequently performed in clinical practice. The roles of the different modifications of CTE are discussed. Evidence- and experience-based recommendations are made to improve early diagnosis and influence prognosis, decrease irradiation of the patient, and lower the costs of investigation. An overview of clinical indications, comparison with other cross-sectional imaging techniques, common technical pitfalls, and limitations are briefly presented.

Historical Background

Enteroclysis was first described by Pesquera in 1929.⁸⁶ Several investigators have modified his technique,⁸⁷⁻⁹³ but the method did not gain popularity because of technical problems, including issues with enteric tubes and inadequacy of fluoroscopic units. It was not until 1971 that Johan Sellink⁹⁴ rejuvenated the technique in Europe and received attention in North America through additional publications by several investigators in the late 1970s and early 1980s.^{12,93,95} His technique was tried by interested radiologists in North America but was not adopted by most of them because of discomfort to patients and the time requirement. Klöppel modified the Sellink method using a lower density, water-soluble enteral contrast and adapted it to monoslice CT.²¹ With the development of multislice CT technology, this method was subsequently modified by Maglinte and colleagues^{52,84,96,97} into a positive enteral contrast CTE and a neutral enteral contrast with IV contrast CTE in several newer studies.

Each modification has distinct strengths and limitations for different clinical indications. An 11% dilution of water-soluble contrast was used for the positive enteral contrast CTE after trials of multiple dilutions of iodinated contrast, and water was used for the neutral enteral contrast with IV contrast CTE.

Figure 39-1 CTE modifications—normal examinations. **A.** Positive enteral contrast CTE. The 11% dilution of water-soluble iodinated contrast with the wide window settings used optimizes visualization of the valvulae conniventes. **B.** Neutral enteral contrast CTE with IV contrast using water. Soft tissue window settings optimize the evaluation of the intestinal wall, mesentery, and solid abdominal organs, a global abdominal examination. Volume (3.5 mL) of neutral enteral contrast used in our protocol includes filling of the colon needed for appropriate staging of Crohn's disease, which includes assessment of the perianal region according to the report of the working party of the 2005 Montreal World Congress of Gastroenterology for inflammatory bowel disease.

Using a wide window CT setting for the positive enteral contrast optimizes visualization of the valvulae conniventes from several dilutions that we have tried in the past.^{51,84,85,98} The use of methylcellulose suspension, which has been withdrawn from commercial distribution in the United States because of contamination as a neutral enteral contrast, was abandoned and replaced with plain tap water for the neutral CTE with IV contrast modification. Absorption is not an issue with CTE compared with CT enterography because of the volume used, the use of a hypotonic agent (glucagon), and continued infusion during CT acquisition (Fig. 39-1). Biscaldi and associates^{27,99-101} have applied the enteroclysis technique using retrograde infusion for selected indications.

Enteroclysis and its cross-sectional modifications, despite their reported accuracy, are mostly performed as a problem-solving tool in tertiary medical centers at present. This method usually follows an orally ingested SB examination (conventional abdominal-pelvic CT with oral and IV contrast, CT enterography, or MR enterography) in patients with negative or equivocal findings or with persistent symptoms despite negative findings. In a minority of specialist centers, in which the various enteroclysis modifications are done regularly, the method is used as a primary diagnostic investigation to exclude or diagnose early SB disease confidently. It is also used in patients with high clinical suspicion of SB disease to decrease radiation burden, decrease cost of work-up,^{22,83-85,102,104,105} and minimize delays in the diagnosis of SB diseases.

Clinical Indications and Comparison with Other Imaging Methods

The lack of a current evidence-based guideline results in inappropriate use and overuse in clinical practice, wasting expenditures by inappropriate referrals, incorrect interpretation, and

duplicative use¹⁰⁵ and resulting in increased cost of investigation, increased radiation burden to patient, and delays in diagnosis, which influence prognosis. Evidence- and experience-based comparisons provide insights on the clinical performance of the different methods of investigation of SB diseases and a rational basis for making recommendations. Although there are limitations in the appraisal of these research studies, they can provide useful guidelines for optimal use of current imaging studies.

SMALL BOWEL CROHN'S DISEASE

In the United States, CT enterography has recently replaced small bowel follow-through (SBFT) as the most frequently used method of SB imaging, particularly for SB Crohn's disease in most practices.^{18,19,26,81,106} With advances in multidetector CT technology, there is validity in this shift.^{19,107} Multidetector CT has simplified evaluation of the small intestine and mesentery compared with the SBFT. The term *CT enterography* was first introduced by Zamboni and Raptopoulos^{11,19,107} in 1997 in reference to a modified abdominal CT technique to address SB Crohn's disease. A large volume of a 2% barium-based or 2% to 5% water-soluble, iodine-based, oral contrast material was administered 1 to 2 hours before scanning. A high dose of IV contrast material and biphasic injection rate regimen of IV contrast were used.

Another orally ingested SB-focused CT method was subsequently described, in which a neutral enteric contrast material (polyethylene glycol [PEG] solution and whole milk) and isotonic oral solution were used.^{108,109} It was not until 2006, when the Mayo Clinic Rochester group reported their experience initially using water and a water-methylcellulose solution, which was replaced by a PEG electrolyte solution and subsequently by low-concentration barium (0.1% w/v ultra-low-dose barium with sorbitol [VoLumen, Bracco Diagnostics, Princeton, NJ]), that CT enterography caught the attention of the radiology

and gastroenterology community.^{110,111} Invited commentaries, which accompanied the reports by Bodily,¹¹² Paulsen,¹¹³ and Maglinte¹⁹ and their colleagues predicted that CT enterography would replace the traditional SBFT as the initial radiologic method of investigation for SB Crohn's and other SB diseases if expertise in DC barium enteroclysis or CTE were not available. Enteroclysis is used as a problem-solving tool in referral centers when questions relevant to management are not fully answered by CT enterography.

The optimal radiologic approach to the patient with suspected, early SB Crohn's disease, or when the clinical indication is to rule out SB Crohn's disease compared with the patient with established SB Crohn's disease, is poorly understood. Although phenotype classification is required when disease is diagnosed, the latter requires staging details for therapeutic decision making, whereas the former requires reliable exclusion of disease. The lag time from the onset of symptoms to confirmation of the diagnosis of SB Crohn's disease has been approximately 36 months.¹¹⁴ Transmural and penetrating phenotypes are usually manifest at the time of diagnosis; it is no longer early SB disease. There has been no recent update on this information because of the more common use of CT enterography, capsule endoscopy (CE), and recent modifications of barium and cross-sectional enteroclysis hybrids. It is likely that the lag time will shorten with these newer, albeit more expensive, techniques.

The use of conventional SBFT as the initial method of examination because of its low cost seems misguided because this likely contributes to the long lag time; it does not reliably exclude early disease and, when an abnormality is suspected, requires additional imaging to confirm the finding.^{15,103} This is one of the reasons for repeated SB imaging with orally ingested methods of investigation before a diagnosis is made. Evidence-based analysis has shown that the negative predictive value of CT enterography is 67% (compared with 48% for SBFT or 63% for MR enterography); these were in patients with aphthoid manifestations of the disease.¹¹⁵ In a report comparing CT enterography with CTE, the conclusion was made that CT enterography "compared favorably" with CTE in the diagnosis of SB Crohn's disease.¹⁰⁷ An invited commentary on the report concluded that the comparison was flawed. The research actually compared two forms of CT enterography, one with enteral

contrast orally ingested (enterography) and the other with enteral contrast hand-injected through a tube (labeled as CTE). Contrast was not continuously infused during CT scan acquisition, as it should be in a technically satisfactory CTE. Distention of the SB was similar, as expected. The disease phenotype was not categorized.¹⁰⁷

An evaluation of published reports does not indicate aphthoid lesions as the only manifestation of SB Crohn's disease with cross-sectional imaging as the method of examination. Radiologists must understand that when reporting the SB examination of patients with Crohn's disease, the disease phenotype, sites of involvement, and severity are categorized. Phenotype classification of SB Crohn's disease using all imaging modalities has been previously reported.¹¹⁶ This is central information for referring clinicians when formulating a course of management. It is no longer enough to state that the findings are consistent with SB Crohn's disease. CTE and MRE have been compared with biphasic barium enteroclysis. CTE has been proven to be significantly superior to enteroclysis in depicting Crohn's disease-associated intramural and extramural abnormalities.^{117,118} The best current evidence-based analysis shows that CTE is a good test for the diagnosis of SB Crohn's disease but barium enteroclysis is required in patients with high clinical suspicion of disease and with a negative CTE.⁶⁰ In the clinical scenario in which there is a high pretest probability (e.g., 85%), a positive CTE result confirms the presence of disease (0.99) but a negative test result is equivocal (0.5). Further investigation with barium enteroclysis was recommended.^{60,119}

A similar conclusion was made in a report comparing MRE with barium enteroclysis and CTE.¹²⁰ In another report, it was concluded that MRE does not perform as well as barium enteroclysis but the additional extraluminal details and absence of ionizing radiation enhances its overall performance.¹²¹ MR imaging is able to depict morphologic changes in the assessment of SB Crohn's disease.¹²²

In another evidence-based comparison between CTE and barium enteroclysis, Minordi and co-workers⁶⁰ concluded that CTE is a good test for the diagnosis of SB Crohn's disease but barium enteroclysis is required in patients with a high clinical suspicion of disease and a negative result on CTE. Further investigation with barium enteroclysis was also recommended (Fig. 39-2).

Figure 39-2 Limitations of cross-sectional imaging in the diagnosis of aphthoid lesions of early SB Crohn's disease. **A, B.** Images show no evidence of hyperenhancement, transmural edema, or wall thickening on CTE done to rule out SB Crohn's disease. Upper and lower endoscopies were not informative. **C.** DC barium enteroclysis shows diffuse aphthoid ileitis with tiny ulcers and beginning submucosal edema evidenced by mild thickening of the plicae circulares (curved arrow). Inflammatory disease markers were abnormal. Patient also had an unexplained lower GI bleed.

Aphthoid lesions are below the spatial resolution of currently used cross-sectional imaging (CT or MR). These abnormalities become perceptible with cross-sectional imaging when submucosal and transmural abnormalities become manifest. They are subtle with DC barium enteroclysis and are easier to diagnose when accompanied by submucosal edema.¹²³⁻¹²⁵ In the symptomatic patient, however, with mucosal hyperenhancement by cross-sectional imaging in an adequately distended segment, particularly when accompanied by submucosal edema, early SB Crohn's disease should be considered, but further confirmation should be recommended.

A false-positive diagnosis of SB Crohn's disease has significant ramifications for patients. The Minordi report⁶⁰ used the biphasic enteroclysis method with methylcellulose, which has been shown to efface surface markings of the SB.^{67,105,126} An insight into the problem of the diagnosis of early SB Crohn's disease was also provided in another evidence-based analysis comparing CT enterography, MR enterography, and the SBFT.¹¹⁵ Phenotype classification using an endoscopic grading of disease severity¹¹⁰ was used as the reference standard. All three methods of investigation showed similar high sensitivity and specificity, but the SBFT was only 76% effective compared with 87% for CT and MR enterographies. The SBFT had the worst interobserver agreement (35%). The negative predictive values (CT enterography 67%, MR enterography 63%, and SBFT 35%) allow an understanding of the problems in the diagnosis of early SB Crohn's disease using nonenteral, volume-challenged examinations and examinations in which mucosal coating is not optimized and abnormalities are smaller than the spatial resolution of the modality. The use of CE early in the investigation may be a rational approach compared with cross-sectional imaging in practices with no expertise in performing DC barium enteroclysis, despite its shortcomings.¹⁰⁴

A comparison between CE and the various modifications of enteroclysis^{46,67,104,127} has further shown that cross-sectional imaging (CT or MRI) does not reveal the aphthae of early SB Crohn's disease when it is the only manifestation of the disease. Several of these evidence-based comparisons predated CE or newer methods of enteroscopy. Most patients had known disease or were highly suspected of having SB Crohn's disease, and the phenotype of SB Crohn's disease was not categorized. In addition, there were heterogeneous tests used as reference standards, including the SBFT, biphasic methylcellulose enteroclysis, and subjective indices. In another meta-analysis, CE was shown to have an incremental yield of 31% more than CT enterography.^{128,129}

In other reports, DC barium enteroclysis and both modifications of CTE compared favorably with CE in the evaluation of suspected Crohn's disease and obscure GI bleeding.^{67,104}

SMALL BOWEL NEOPLASMS

Although the small intestine represents almost 75% of the total length of the GI tract and almost 90% of its mucosal surface, SB neoplasms remain rare; they account for less than 5% of all GI tumors.¹³⁰ Colon cancer is 50 times more common than SB cancer.¹³¹ Adenocarcinoma, mostly located in the duodenum and proximal jejunum, makes up 30% to 40% of cancers. Carcinoid, mostly in the ileum and uncommon in the proximal SB, makes up 35% to 42%; lymphomas, mostly in the ileum and jejunum, approximately 15% to 20%; and sarcomas, which are evenly distributed, approximately 10% to 15%.¹³²

The incidence of SB cancer has increased during the past several decades—fourfold for carcinoid, less dramatic for adenocarcinoma and lymphoma, and stable for lymphoma. The incidence is higher in North America, Western Europe, and Oceania than in Asia.¹³³ An increase in the 5-year relative survival (U.S. SEER data, 1992-2005), particularly for carcinoid (80.7%), has been noted.¹³⁴ This is secondary to novel adjuvant therapies and not to imaging. The relative contribution of imaging to this improvement has not been evaluated. The relative survival is 64.1% for lymphoma, 57.9% for sarcomas, and 28.0% for adenocarcinoma. There is, however, no significant change in the long-term survival for any of the histologic types.¹³⁴ This has been attributed to most patients being diagnosed late, with local extension or distant tumor spread at the time of surgery and the long interval between the onset of symptoms and time of diagnosis. Reports have shown 40% local spread and 30% distant spread (Fig. 39-3).^{135,136} A prior analysis of why these delays occur showed that the major delay was after medical help was sought, longest after a false-negative result of radiologic examination.¹³⁶ In this report, the delay because of the patient failing to report symptoms was less than 2 months, the physician not ordering an appropriate diagnostic test about 8 months, and the radiologist failing to make the diagnosis approximately 12 months. This is a lag time of approximately 2 years, longest after a false-negative result of a radiologic examination.¹³⁶

The vague clinical presentation of these tumors, usually abdominal pain and less often GI bleeding, is also contributory.

Figure 39-3 Late diagnosis of SB malignancies. Shown is a CT scan of the abdomen and pelvis with IV contrast in a patient with chronic recurrent nausea and vomiting. Coronal images show a mass in the proximal jejunum (arrow) consistent with proximal SB malignancy; also note liver metastases. Surgical pathologic findings showed adenocarcinoma.

These data underlie the need for a reliable method of examination when there is a possibility of SB neoplasm or unexplained abdominal symptoms and upper and lower GI evaluations are unrevealing. The role of imaging in these patients is to rule out or confirm early SB tumor reliably. SB tumors are rare and frequently underdiagnosed or diagnosed late (see Fig. 39-3). Curative resection remains the only curative therapy for SB malignancies.¹³⁷ There is no rigorous imaging comparison evaluating multiple peroral SB examinations and intubation-infusion distended SB modifications. A prior comparison of orally ingested SB barium examination with enteral volume-challenged examinations showed the sensitivity of orally ingested SB examination to be 61%, whereas that of enteroclysis was 95%.¹³⁸ This result highlights the difference in diagnosing filling defects when the SB is distended.

There have been no rigorous head to head comparisons between CTE and MRE or between CT enterography and MR enterography. MR imaging is frequently recommended because of the lack of ionizing radiation.¹²⁰ Both CTE and MRE have been shown to have high accuracies, more than 90%, but the discomfort of intubation has been a deterrent, and hence the rationale for recommending MR enterography.^{28,57,97,139-141}

However, this deterrent is not an issue when appropriate conscious sedation is administered and may even be preferred by patients who do not want to drink the large amount of

oral contrast and want to have no recall of their experience.¹⁴² There is an important factor for radiologists to consider—a lack of knowledge on the part of ordering physicians who want to do what is best for their patients but do not understand which imaging study is the most reliable to answer questions relevant to patient work-up and management in the evaluation of SB diseases, particularly when the possibility of SB neoplasm is concerned. Radiologists must function as consultants, so that when orally ingested SB examination results are not informative and unexplained abdominal symptoms persist, recommendation should be made to refer these patients to centers in which enteral, volume-challenged examinations are routinely performed.

An added role of CTE in the work-up of SB neoplasms is to guide the enteroscopist about which route to take in the evaluation of patients who may require biopsy or endoscopic removal of SB lesions. When multiple defects are present, the precise location of the largest lesion is readily estimated by CTE using currently available software. Although this can be done with neutral enteral CTE, the positive enteral CTE modification is simpler to use with vessel analysis software when required, although localization can be frequently estimated (Fig. 39-4). Changes in the practice of radiology in the past 3 decades and knowledge of the long-term survival of patients with malignant SB tumors are reminders to referring physicians

Figure 39-4 Use of CTE to guide enteroscopic approach in a patient with multiple SB abnormalities. A. Coronal image of a positive enteral contrast CTE on a patient with Peutz-Jeghers syndrome done because of symptoms of mechanical SBO. Multiple filling defects are seen throughout the mesenteric SB and duodenum. The largest (arrow) showed intermittent intussusception on real-time (fluoroscopic) phase of the examination. **B.** Multiple small polyps in the duodenum, proximal jejunum, and midileum. **C.** Enteroscopic image shows the largest polypoid mass (arrow). **D.** Hamartomatous mass (arrow) removed during double-balloon enteroscopy done using the oral approach. The use of vessel analysis software allows determination of the distance of an abnormality from the ligament of Treitz or ileocecal valve. (From Maglinte DD: Fluoroscopic and CT enteroclysis: Evidence-based clinical update. *Radiol Clin North Am* 51:149–176, 2013.

and radiologists of the important role of imaging in the evaluation of SB tumors.¹⁴¹

SMALL BOWEL OBSTRUCTION

SB obstruction is a common clinical condition, often presenting with signs and symptoms similar to those seen in other acute abdominal disorders. Once suspected based on the patient's clinical history and physical examination, radiologists must verify or exclude the presence of obstruction and provide cogent information on the site, severity, and probable cause of the obstruction and presence of strangulation.¹⁴³⁻¹⁴⁷ Although initial reports showed high accuracy of CT of the abdomen and pelvis with oral and IV contrasts in the diagnosis of SBO,^{148,149} a subsequent evidence-based comparison showed an overall accuracy of 65%.¹⁵⁰⁻¹⁵² In this analysis, however, the accuracy of conventional CT increased to 81% for high-grade and complete obstruction. With low-grade obstruction, accuracy was 48%, statistically similar to the sensitivity of abdominal radiography for SBO.¹⁵³

These patients have recurrent symptoms, and additional conventional CT examinations are often obtained until the obstruction becomes severe enough to be diagnosed. In patients with symptoms of recurrent low-grade adhesive obstruction, following an initial negative orally ingested CT examination usually done in the emergency department, a recommendation should be made to the referring physician that if a further investigation is needed, these patients should be referred for enteral volume-challenged examinations. In this subset of patients, similar to patients with suspected SB Crohn's disease or tumor, repeated examinations that are unable to rule out obstruction reliably are done before appropriate imaging is

requested. Findings of adhesions are often present in retrospect but are not confidently diagnosed because of the lack of an appreciable transition point; the latter is exaggerated with enteral, volume-challenged examinations. This diagnosis should be made even when nonobstructive, because these are known to cause symptoms of recurrent or chronic abdominal pain in patients with prior abdominal surgery (Figs. 39-5 and 39-6).

Dense, anterior, parietal peritoneal adhesions increase the risk of bowel injury during laparoscopy and may require alternative trocar insertion sites.¹⁵⁴ The number and sites of SBO and length of the SB proximal to the first point of obstruction assist the surgeon in deciding whether an adequate absorptive surface is available for the formation of an ostomy or bypass (generally, 125 cm).^{143,145,146} Conventional CT and other nonenteral, volume-challenged examinations are not sensitive for lower grades of SBO that present usually in the subacute phase.^{103,150-152,155} CTE is the most accurate method for the further investigation of these patients and in those with SBO diagnosed by conventional CT, in whom additional, management-relevant questions are not answered.^{145-147,150} In the former group of patients, symptoms frequently subside with nonsurgical management.

Confirmation of the diagnosis by CTE prevents the repeated performance of orally ingested enteral contrast SB CT or MR examinations. These examinations neither confidently diagnose nor exclude low-grade obstruction in the appropriate clinical setting. A larger volume of neutral oral contrast may minimize this disadvantage, but patients with this condition experience nausea and sometimes vomit with the volumes given for CT enterography. Not infrequently, they are unable to finish ingesting the optimal volume required. By directly infusing contrast into the SB and providing a fluid volume challenge, the presence

Figure 39-5 Conventional CT and CTE in low-grade small bowel obstruction. A, B. There is no evidence of a gradient or transition point to suggest mechanical obstruction in a patient with symptoms of recurrent SBO. **C, D.** CTE of the same patient demonstrates the transition point and prestenotic dilation from an anterior parietal adhesive obstruction posterior to the right rectus muscle. Interloop (visceral) adhesions (arrowhead) are noted in segments posterior to the parietal adhesive obstruction.

Figure 39-6 Demonstration of transition point and prestenotic dilation. A. Coronal image of CT abdomen and pelvis with orally ingested neutral contrast shows filling loops of the SB, including distal loops, but no evidence of mechanical obstruction seen in patient with tuberculous stricture (same patient as in Fig. 39-1). **B.** Stricture now apparent (arrow) with prestenotic dilation during enteral volume challenge. Note the so-called dirty feces sign from inspissated debris. (From Gollub MJ, Maglinte DD: *CT enterography and CT enteroclysis*. In Shirkhoda A [ed]: *Variants and Pitfalls in Body Imaging*, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2011, pp 328–362.)

of an existing low-grade obstruction, gradient, or prestenotic dilation is exaggerated and reliably diagnosed; vomiting is avoided by controlling infusion rates fluoroscopically and understanding several variables involved in enteroclysis that require fluoroscopic guidance (see Fig. 39-6).^{143,146} Even when no gradient is observed, demonstration of subtle deformities such as luminal narrowing and fixations are easier to appreciate. Real-time (fluoroscopic) observations add to the confidence in making or excluding the diagnosis.

This observation adds to the morphologic details provided by multiplanar CT. Cross-referenced assessment provides more precise assessment of the location and characterization of the cause. The positive enteral CTE modification is preferred for this subset of patients, although this condition can be diagnosed also with neutral enteral CTE with IV contrast. The lack of real-time control by the radiologist on the rate of infusion and volume needed for neutral enteral CTE add to the possibility of vomiting in this group of patients, which makes this modification less ideal. The method can be modified, particularly in patients with inflammatory SB disease with low-grade obstructive symptoms, with indirect monitoring of the infusion rates; this requires fluoroscopic guidance. Determining the optimal infusion rates on either modification is difficult and requires experience because there are several variables that influence it, and each patient is different.⁸⁵ In the subset of patients with recurrent symptoms, a subtle gradient or transient stasis may be observed fluoroscopically and may not be depicted on the CT image.

Correlating the fluoroscopic observation and the anatomic information depicted by multiplanar CT allows a confident report of low-grade adhesive obstruction from a parietal or visceral adhesion or both. Neutral enteral with IV contrast CTE excels in evaluating mural abnormalities in addition to the mesentery and solid viscera. In patients in whom the obstruction has resolved, adhesions are still reliably visualized on CTE. When patients with a history of malignant neoplasm and prior abdominal surgery present with an SBO, radiologists are often faced with the difficult task of determining the exact cause of

the obstruction. CTE provides the necessary intraluminal and extraluminal information to help differentiate SBO caused by seeded or hematogenous metastases from that caused by radiation exposure or postsurgical adhesions.^{6,96,156,157} Thus, in addition to anatomic information regarding tumor size and location, CTE can reliably assess for the presence of associated low-grade obstruction.¹⁵⁸

There is a subset of patients with SBO for whom surgeons prefer initial conservative management (i.e., tube decompression of the distended SB) over surgery.^{159,160} These are patients with the following: (1) SBO in the immediate postoperative period; (2) a history of prior abdominal surgery for a malignant tumor; (3) a prior history of radiation therapy; or (4) Crohn's disease with prior surgery. Further characterization of the severity and nature of the obstruction are of value for management. The use of the triple-lumen, long decompression-enteroclysis (Maglinte Long Tube; MDEC, Cook, Bloomington, IN) has allowed us to participate in the management of these patients by preliminary decompression of the distended SB, performance of a diagnostic CTE, and further long-tube decompression after the examination.^{84,85,143,145,146,161-163}

The use of positive enteral CTE allows assessment of the cause and severity of the obstruction in addition to more efficient, long-tube suction (Fig. 39-7).^{143,146,164} Participation in the care and management of this subset of patients is important for radiologists to consider; it could help change the low prestige and perception of mediocrity of radiology as a specialty by other physicians.^{165,166}

Our technique of examination is modified in patients with a prior history of pancreatoduodenectomy (Whipple procedure). They may present with symptoms in the subacute or chronic setting unexplained by cross-sectional imaging, which is now the routine examination of the postoperative pancreas,^{167,168} and questions relevant to management require evaluation of hepaticojejunal, pancreatojejunal, gastrojejunal, and pylorojejunal anastomoses.¹⁶⁹⁻¹⁷⁵ The catheter tip and balloon are positioned immediately distal to the gastroesophageal junction and retracted until mild resistance is met to

Figure 39-7 Use of long tube decompression in postoperative examinations. **A, B.** Axial images of CT of the abdomen and pelvis in a patient with symptoms of SBO, taken in an outside institution, show findings consistent with mechanical SBO. Laparoscopic exploration did not show a point of mechanical obstruction. **C.** Abdominal radiograph obtained following initial nasogastric suction with long tube (note catheter tip in the gastric antrum) at the Indiana University Hospital. **D.** Overnight suction after long tube advanced to proximal jejunum shows decrease in distention of SB loops. **E.** Axial CT section of positive enteral CTE shows mural thickening and narrowed lumen at the level of the proximal ascending colon (arrow). **F.** Coronal image of CTE shows an annular lesion, raising the possibility of carcinoma (arrow). Colonoscopy and biopsy showed tuberculous colitis simulating malignancy (patient had a false-negative result from an incomplete colonoscopy at the outside institution).

prevent gastroesophageal reflux during controlled infusion. This modification allows for the evaluation of the pylorojejunal anastomosis and hepaticojejunal and pancreatojejunal anastomoses, as well as distal segments of the SB in real-time and cross-sectional images. This modification has been termed the *CT Whipplegram* for lack of a better name (Fig. 39-8). It simplifies the evaluation of all the anastomoses and the distal SB when partial obstruction enters the differential diagnosis to explain postoperative symptoms in those with prior lower abdominal surgical procedures. We also use this modification in patients with prior Billroth procedures or prior partial or total removal of the upper GI tract and a Roux-en-Y anastomosis (Fig. 39-9). The balloon and catheter tip are positioned immediately distal to the anastomosis. The esophageal anastomosis is evaluated initially using enteral contrast with the catheter tip above it before advancement of the catheter. This simplifies the examination of this subset of postsurgical patients, in whom examination is difficult with orally ingested contrast with conventional fluoroscopic or cross-sectional imaging. The timing of surgical intervention, as well as the optimal method of radiologic investigation in patients with incomplete, open loop SBO, has changed during the past 2 decades.^{47,146,176}

Evidence-based analysis has shown the added value of CTE over other methods of examination.^{104,150-152,155} Reliable exclusion or confirmation of the diagnosis, detection of multiple levels of obstruction, and objective classification of severity and cause are useful information provided by CTE in the evaluation of these patients. Advances in imaging techniques have changed how work-ups are planned for patients with suspected SBO.

Conventional CT has high sensitivity in diagnosing high-grade obstruction and is helpful in confirming the presence or absence of strangulation; several reports have confirmed the value of CT for this indication (Fig. 39-10).^{143,144-152,164,177-181}

Although the specificity of contrast-enhanced CT for intestinal ischemia has been reported to be as low as 44%, its high sensitivity (90%) and negative predictive value (89%) are helpful in making decisions concerning continued nonoperative management versus surgery.^{177,182-187} The dictum, “Never let the sun rise or set on small bowel obstruction,” once popular among general surgeons because of the feared complication of strangulation and the clinical difficulty associated with its preoperative recognition, is now outdated.^{188,189}

MISCELLANEOUS INDICATIONS

When the cause of blood loss from the GI tract is still not clear after upper and lower endoscopies (obscure GI bleed), studies have recommended several options, each with their own proponents, which may present as a long-term and difficult management problem. Angioectasias are the most common cause of obscure GI bleeding and are only visible on endoscopy or potentially on arterial phase, catheter-based or CT angiography. Imaging studies are insensitive to these small, flat, vascular lesions. A three-phase CT enterography has been described, with the goal of detecting angioectasias and other arterial phase-dominant lesions.¹⁹⁰⁻¹⁹² The radiation burden (effective dose, 59 mSv/examination) and the relative risks should be considered in young patients. Unless the patient is slowly or actively

Figure 39-8 CT Whipplegram. **A.** Axial CT of a patient after recent Whipple procedure. This was done for a neuroendocrine tumor with persistent vomiting and nonresolving fluid collection in the perihepatic space that was referred for CTE to exclude distal SBO and leak at the level of a pancreaticojejunostomy. Note reactive inflammatory changes to the right of the dilated pancreatic duct (*arrow*). **B.** Coronal image shows fluid collection and drainage catheter in the right perihepatic space. **C.** Scanogram showing uniform distention of the SB with antireflux balloon of enteroclysis catheter immediately distal to the gastroesophageal junction. **D.** Coronal CTE image shows normal caliber of biliopancreatic limb (*arrow*). **E.** Coronal image shows a patent pyloroduodenal anastomosis (*arrow*) without evidence of a leak. **F.** Axial image shows small amount of pneumobilia and contrast in the intrahepatic tributary. **G.** Coronal image of CTE shows small amount of leak to the left of the hepaticojejunostomy (*arrow*). **H.** Coronal image of CTE shows no evidence of distal mechanical SBO. The *arrow* points to a well-delineated biliopancreatic limb.

Figure 39-9 CTE in the evaluation of late postsurgical complications. **A, B.** Axial CT images with oral and IV contrast in a patient with abdominal distention, nausea, and vomiting and a history of prior ulcer surgery. An apparent abnormality is seen in the proximal SB. The possibility of intussusception and a mass were reported. **C.** Image during fluoroscopic phase of positive enteral CTE shows the balloon distal to the gastroesophageal junction. **D.** Frontal radiograph shows dilated gas and fluid-filled proximal SB, without evidence of a mass or intussusception. Stasis was seen at fluoroscopy at this level, suggesting postsurgical dysmotility. **E, F.** Axial and coronal images of CTE show dilated proximal SB loop compatible with dysmotility noted on real-time (fluoroscopic) evaluation, without evidence of a mass or intussusception. An abnormality noted is secondary to admixture defects secondary to stasis related to dysmotility from a prior Billroth 1 procedure done with vagotomy. (Data from Gollub MJ, Maglinte DD: CT enterography and CT enteroclysis. In Shirkhoda A [ed]: *Variants and Pitfalls in Body Imaging*, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2011, pp 328–362).

Figure 39-10 Strangulation in intestinal obstruction. **A.** Axial image of CT in a patient with abdominal pain, nausea, and vomiting. The arrow shows a nonperfused segment of the proximal jejunum in late arterial phase CT acquisition. Note the abnormal superior mesenteric vascular course, which suggests midgut volvulus. **B.** Axial at the level of the superior aspect of the pelvis shows the absence of perfusion of mesenteric SB, consistent with infarction confirmed at surgery.

bleeding at the time of acquisition, CT enterography or CTE will not demonstrate the angioectasias that can be seen on endoscopy or SB enteroscopy. CTE has the advantage of reliably excluding small SB neoplasms because it examines the entire small intestine and mesentery. In centers in which expertise in performing DC barium air enteroclysis is available, it should be performed when NSAID enteropathy is a clinical possibility and cross-sectional imaging is not informative. A history of heme-positive stools or hematochezia indicates that mucosal abrasion or ulceration is present, and examinations that depict the mucosa should be considered (e.g., DC barium enteroclysis in the nonemergent setting).

The need to perform an SB examination in the emergent setting on a bleeding patient after endoscopic examinations with negative results make CT enterography a practical approach after the patient is stabilized following a negative endoscopic examination. DC barium enteroclysis should be recommended for patients with equivocal or noninformative cross-sectional imaging studies or CE with a heme-positive stool examination. This method allows for the exclusion of SB neoplasm, early Crohn's disease, NSAID enteropathy, and other SB abnormalities (Fig. 39-11).

Another observation obtained during fluoroscopy in the subset of patients with recurrent abdominal pain is that in some patients with visceral hypersensitivity or irritable bowel syndrome (IBS), the abdominal symptoms are reproduced during contrast infusion and distention of the SB. This confirms the clinical suspicion.^{2,193} Lack of reproduction of abdominal symptoms, however, does not exclude the diagnosis, because no

Figure 39-11 Role of imaging in occult GI bleeding. Teenage patient with heme-positive stools with negative results by upper and lower endoscopies, CT enterography, and Meckel scan and CE. DC barium enteroclysis shows a small Meckel diverticulum (arrowhead). Small ulcerations were seen in the surgical specimen. Enteroclysis with careful fluoroscopic evaluation is the most accurate method of diagnosing Meckel diverticulum. (Data from Maglinte DD, Elmore MF, Isenberg M, Dolan PA: Meckel diverticulum: Radiologic demonstration by enteroclysis. *AJR* 134:925-932, 1980.)

scientific validation of this fluoroscopic observation during enteroclysis has been reported; the predictive values are therefore difficult to evaluate scientifically. In our experience, it may coexist with an SB anatomic abnormality and may be important information for management. The primary role of imaging in the investigation of patients suspected of IBS is to exclude morphologic SB abnormality. No guidelines exist for imaging IBS; this awaits further research.¹⁹⁴

Technical Pitfalls and Limitations

The discomfort and pain associated with nasoenteric intubation is the most significant factor that has limited the implementation of enteroclysis and its cross-sectional modifications in clinical practice, despite its diagnostic accuracy.¹⁹⁵ The fact that patients have been able to undergo enteroclysis without conscious sedation does not indicate that it is a well-tolerated procedure. A stoic patient can undergo the examination but cannot forget the discomfort and pain endured during the procedure. Several studies have shown that physicians underestimate discomfort during intubation procedures and, like their patient, are unwilling to undergo intubation procedures on themselves without sedation or analgesia.¹⁹⁶⁻²⁰¹ This basic pitfall, seemingly forgotten by most radiologists, is obviated by the use of conscious sedation, which allows patients to tolerate unpleasant procedures while maintaining adequate cardiopulmonary function and their ability to respond purposefully to verbal commands.²⁰² In practices which conscious sedation is not practical and expertise in intubation is available, the use of a parenteral sedative (e.g., diazepam [Valium]) and a local intranasal anesthetic gel (a 3-mL combination of tetrahydrozoline 0.1% and tetracaine 2%) makes enteroclysis intubation acceptable.

Many patients tolerate enteroclysis with the use of only a sedative as initially reported²⁰³; however, their recall of nasal pain, gagging, and occasional vomiting are good. A recent survey of the safety and patient-reported effectiveness compared using only a sedative and intranasal gel with a regimen combining an amnesic, analgesic, and local nasal anesthetic and intranasal gel showed that the latter is better tolerated; when an adequate amnesic dose is administered, patients forget the discomfort.¹⁴² The addition of a local nasal anesthetic to the amnesic-analgesic medication likely explains the success of our busy, patient-friendly enteroclysis practice.¹⁴² Unless contraindicated, our conscious sedation protocol uses a combination of midazolam (2 to 7 mg) given in 1-mg increments. An analgesic (fentanyl, 50 to 150 µg), given IV in 25-µg increments and carefully monitored by a radiology sedation nurse, may be administered selectively if needed for severe pain because it decreases gastric and small bowel motility. This regimen is safe and effective. In most patients, all that is required is the nasal numbing spray and amnesic. Radiologists who want to start a conscious sedation protocol for enteroclysis should make arrangements with interventional radiology sections who have used dedicated radiology nurses for their procedures.²⁰⁴ Smaller catheters also decrease discomfort, but currently available small catheters do not have the balloon attachment to prevent reflux; the use of 13-Fr enteroclysis catheters with a balloon attachment (Maglinte enteroclysis catheter; Cook) is therefore preferred.

Performance pitfalls of enteroclysis relate more to experience and familiarity with catheters, balloons, pumps, and

various oral contrast agents, which have all been described.¹⁸ Nuances related to catheterization, rates of infusion, and type of modification to be used, depending on the clinical indication, have also been described.^{52,83-85,205,206} It would be helpful if 2 to 3 days are spent observing a practice that performs these procedures daily. There has been a prevalent misconception that enteroclysis is simply positioning a nasoenteric catheter and infusing contrast, which is the recipe for an “enterocrisis!” All patients are different, and optimizing the protocol for every modification of enteroclysis, depending on the clinical indication and addressing multiple technical variables, requires an understanding of basic principles; unfortunately, this is not intuitive. Understanding the various pitfalls and limitations in the evaluation of SB disease and optimizing SB imaging techniques decrease errors in the performance of these procedures.

Comments

CTE is a hybrid technique that combines the methods of fluoroscopic, intubation-infusion SB examinations with those of abdominal CT. The use of multidetector CT technology has made this a versatile examination that has evolved into two distinct technical modifications, with their specific clinical applications.

The efficacy of imaging procedures in confirming or confidently excluding SB disease is not frequently considered in the investigation of SB diseases by radiologists and referring physicians. The influence on the referring physician’s diagnostic confidence when formulating a course of management by using an SB examination and how it is reported is also infrequently considered by radiologists, which may involve looking beyond reported statistical accuracy.²⁰⁷ Hence, it is not uncommon to see patients with several imaging examinations previously done before a diagnostic examination is performed or its confident exclusion is established. This situation also explains requests for a second reading or opinion on examinations already reported. Imaging is a rapidly growing part of health care spending, and an overall consideration of costs when looking at the effectiveness of SB diagnostic procedures is not given serious thought; what is convenient and revenue-producing currently seem to be the primary considerations.

Not infrequently, peroral ingested SB examinations that do not involve direct participation by radiologists are done several times before a diagnosis is made. Available guidelines do not include assessment of the evidence of efficacy of diagnostic imaging on diagnostic confidence and patient management.²⁰⁷

When ordering SB imaging procedures, unlike for other abdominal organs, it should be realized that the incidence of SB diseases is low and the clinical presentation not specific. Thus, examination methods with a high negative predictive value

and high sensitivity should be performed first if expertise is available.*

In SB imaging, the examination that reliably excludes SB disease or confirms early or small abnormalities and gives the referring physician confidence in formulating a treatment should be given primary consideration. Procedures that provide equivocal or inconclusive information and do not provide clinicians the confidence to formulate a management plan should not be repeatedly used. Enteroclysis and its modifications, when done appropriately, with due consideration for patient comfort, fulfills this role. Few reports that show the superiority of enteroclysis and its modifications have been based on well-controlled trials.

Only rather recently have clinically important advances been based predominantly on evidence generated from well-controlled trials, which may not be possible with SB imaging.^{165,207-218} The number of well-controlled trials in SB imaging is few and will likely remain this way. Referring physicians and radiologists must rely on the art of medicine to fill in the gaps.²⁰⁹ In the literature, there is enough clinical evidence to show the superiority of enteroclysis and its modifications over orally ingested enteral SB examinations.

Summary

The diagnostic evaluation of SB diseases has changed profoundly during the past few decades.¹⁰² The important role of radiology in the investigation of SB diseases remains poorly understood by referring physicians who treat the patients and radiologists who perform the examinations. An important factor for radiologists to consider is that there is a lack of knowledge on the part of ordering physicians, who want to do what is best for their patients but do not understand which imaging study is the most reliable to answer questions relevant to patients’ work-up and management in the evaluation of SB diseases. This is particularly true when the possibility of an SB neoplasm is concerned or there is a recurrent, low-grade adhesive obstruction.

Radiologists must function as consultants so that when orally ingested SB examination results are not informative, and unexplained abdominal symptoms persist, these patients should be referred to centers in which enteral, volume-challenged examinations are routinely performed. Evidence- and experience-based analyses have shown that there are no shortcuts to reliable SB imaging. When properly performed, the added value of the different modifications of CTE to patient care is not difficult to understand. Examinations that distend the SB diagnose smaller and early lesions and allow confident exclusion of SB disease, an important factor to consider when imaging the patient for possible SB disease.

Bowel Ischemia and Vasculitis
Infections
Small Bowel Obstruction

Summary

Small bowel radiology has undergone dramatic changes in the past 2 decades. Despite recent advances in small bowel endoscopy and video capsule technology, radiologic imaging remains an important means of evaluating patients with suspected or established small bowel disease.¹⁻⁵ Cross-sectional imaging techniques are used to investigate extraluminal abnormalities and intraluminal changes and have gradually replaced barium contrast examinations for many indications.⁶⁻¹³

Magnetic resonance imaging (MRI) has many properties that make it well suited to imaging of the small bowel, such as the lack of ionizing radiation, improved tissue contrast that can be achieved by using a variety of pulse sequences, and the ability to perform real-time functional imaging.¹⁴⁻¹⁸ Moreover, MR modalities allow visualization of the entire bowel without overlapping bowel loops as well as the detection of intra- and extraluminal abnormalities. These morphologic MR findings, combined with contrast enhancement features and functional information, help make an accurate diagnosis and consequently characterize small bowel diseases. These features dramatically change the image interpretation process.¹⁸ Radiologists must focus on morphologic findings and functional data of small bowel motility to exploit MR capabilities fully. Optimal distention of the small bowel loops is crucial for the correct evaluation of the bowel wall because collapsed bowel loops may hide lesions or mimic disease by mistakenly suggesting that the collapsed segments are actually an abnormality-related thickened bowel wall.¹⁹⁻²¹

Two main techniques have been used to achieve small bowel distention, MR enteroclysis with infusion of the contrast material through a nasojejunal tube and MR enterography with

oral administration of contrast material.¹⁸ There is a general preference among radiologists for performing enterography over enteroclysis; however, this preference is controversial.^{18,21-23} MR enteroclysis is known to provide better depiction of endoluminal lesions in the small intestine than that achieved at MR enterography performed with an oral contrast agent.²¹ It is also generally acknowledged that MR enteroclysis provides optimal small bowel distention and allows more accurate detection of strictures.²¹⁻²³ However, nasointestinal intubation for MR enteroclysis may cause patient discomfort, and it involves various technical and logistical difficulties, as well as exposure to radiation. MR enteroclysis performed with the continuous administration of an enteric contrast agent is not possible at all facilities.

Although Crohn's disease is the primary indication for MR enterography because many patients require multiple follow-up imaging examinations, MR enterography is performed with increasing frequency for the evaluation of other small bowel diseases. MR imaging offers detailed morphologic information and functional data of small bowel disease, thereby allowing the diagnosis of early or subtle structural abnormalities and guiding patient therapy.

Technical Considerations

ENTERAL CONTRAST AGENTS FOR MAGNETIC RESONANCE IMAGING

A number of enteral agents have been proposed for use in small bowel MR imaging. The most important features of enteral contrast agents include uniform and homogeneous opacification, adequate distention of the small bowel lumen, high contrast between the lumen and small bowel, low cost, and absence of serious adverse side-effects.

There are three main groups of enteral agents. The signal intensity that results from their use varies according to the pulse sequence used.^{24,25} Positive contrast enteral agents, which yield high signal intensity on T1-weighted images, include gadolinium chelates,²⁵ manganese ions,²⁶ ferrous ions,²⁷ and foods such as blueberry juice.²⁸ Although these enteral agents can show mural thickening on T1-weighted images,²⁹ they inevitably are limited regarding the detection of more subtle mucosal or wall hyperenhancement after the intravenous injection of gadolinium-based contrast material. Consequently, their routine use is not recommended.

Negative contrast enteral agents, which yield low signal intensity on T2-weighted and especially T2*-weighted images, constitute solutions with superparamagnetic iron oxides (SPIOs), including nanoparticles of maghemite in bentonite matrix, and ultrasmall SPIOs (USPIOs).³⁰ Currently, the only negative contrast agent commercially available in the United States is ferumoxsil oral suspension, which is used in MR cholangiopancreatography to reduce the signal from

Figure 40-1 Normal MR enterography findings. Iso-osmotic polyethylene glycol–water solution (biphasic contrast agent) acts as a positive intraluminal contrast agent (bright lumen) on (A) true FISP as a negative agent (black lumen) on a 3D T1-weighted fat-saturated VIBE image (B). Normal valvulae conniventes (arrows) in a well-distended jejunum are visible.

surrounding bowel. The high signal intensity of inflammation in the bowel wall and in the surrounding fat may be more conspicuous on T2-weighted images obtained with a negative contrast agent because of the greater contrast achieved between the high signal intensity of inflammation and the low signal intensity of the lumen. Side effects (observed in 5% to 15% of cases) associated with these enteral agents include poor palatability of the agent, nausea, vomiting, and rectal leakage.²⁴ Moreover, the low signal intensity of intraluminal contrast on T2-weighted images and associated susceptibility effects may reduce the conspicuity of the normal small bowel wall, low signal intensity lesions, such as carcinoid tumors, and intraluminal abnormalities.

The third group of agents are biphasic enteral contrast agents, which have been most widely tested and are most commonly used for MR enteroclysis and MR enterography.³¹⁻³³ They produce low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. The low signal intensity of these agents on T1-weighted images improves the contrast between the bowel lumen and hyperenhancing mural inflammation or masses after intravenous administration of contrast material (Fig. 40-1). The marked contrast between the lumen and dark bowel wall on T2-weighted images improves the detection of endoluminal abnormalities and more effectively highlights transmural ulcers.^{34,35} Commercially available biphasic enteral agents include water, polyethylene glycol, barium sulfate (VoLumen; E-Z-Em/Bracco, Lake Success, NY), and nonosmotic agents such as locust bean gum and methylcellulose.^{36,37} Polyethylene glycol is a high-osmolar, nonabsorbed, nonfermented contrast medium that has been shown to provide excellent intraluminal contrast and luminal distention,³⁸⁻⁴⁰ although this enteral agent may cause mild diarrhea. Barium sulfate, an enteral contrast agent that contains sorbitol, whose osmotic properties cause it to retain water, has also proved to be effective.⁴¹ Barium sulfate and water–polyethylene glycol solution are both superior to plain water

and water–methylcellulose solution for achieving optimal small bowel distention.⁴¹

TECHNIQUE

Optimal distention of the small bowel loops is crucial for the correct evaluation of the bowel wall. This is because collapsed bowel loops may obscure lesions or mimic disease by mistakenly suggesting that the collapsed segments are actually an abnormality-related thickened bowel wall.⁴²

MR enteroclysis has been shown to depict early disease and the number of involved segments more accurately,¹⁸⁻²² whereas enterography is more time-efficient for radiologists and other staff because nasojejunal tube placement is not required. Although jejunal distention is frequently suboptimal,¹⁸⁻²² the ileum, which is the most common site of small bowel involvement in Crohn's disease and the region of most interest to clinicians, is usually well depicted. Enterography also eliminates radiation exposure and the technical and logistical difficulties of nasojejunal tube insertion, and it removes a potential barrier to patient compliance with future examinations.

Enterography techniques require the ingestion of a large amount of fluid that fills the stomach and small bowel. Patient tolerance is the current limitation. As yet, there is no consensus on the optimal volume of oral contrast medium needed for an enterographic examination⁴⁰⁻⁴⁵; a volume of 1350 to 1500 mL is adequate in most cases.

Although rapid transit (<20 minutes) to the right colon has been observed, there is a delay of at least 40 to 60 minutes from contrast material ingestion to imaging in most patients.⁴⁶ Although some authors⁴⁶⁻⁴⁸ advocate imaging the patient twice (e.g., after 20 minutes for optimal visualization of the distended jejunum and after 45 minutes for the ileum), a single acquisition performed 40 minutes after the ingestion of oral contrast material is effective and practical in terms of patient compliance and efficient time use of the MR imager.^{7,18}

MAGNETIC RESONANCE IMAGING PROTOCOL AND PULSE SEQUENCES

A preprocedural fast of 4 hours is recommended³⁶ because fasting reduces the amount of food residue and debris in the intestinal lumen, which may mimic mass lesions or polyps. Patients are imaged in the supine or prone position. The prone position helps separate bowel loops, provide maximal bowel coverage on coronal images, and decrease the imaging volume.^{41,48} Although the prone position does offer better distention, it does not translate to better lesion detection.⁴⁸ The supine position affords greater patient comfort and is indicated for patients with abdominal pain, stomas, and/or abdominal wall fistulas.

For the MR enterography protocol, an initial thick slab T2-weighted MR cholangiopancreatographic study helps assess small bowel distention. If there is inadequate distention of the ileum, the patient can return to the waiting room to drink more oral contrast material. The MR technical protocol is shown in Table 40-1.

Antiperistaltic agents such as hyoscine butylbromide (Buscopan; Boehringer Ingelheim, Ingelheim, Germany) or glucagon (Glucagen; Novo Nordisk, Bagsvaerd, Denmark) are used intravenously to eliminate peristalsis and reduce motion artifact.¹⁸ Achieving reduced peristalsis is of considerable importance for the T1-weighted 3D sequences performed after the administration of intravenous contrast material and may help limit intraluminal flow artifacts on images obtained with the half-Fourier acquisition. I administer an initial 10 mg of hyoscine butylbromide or 0.2 mg of glucagon immediately before the examination starts to reduce intraluminal flow voids. The patient receives an additional dose of the same strength prior to gadolinium-based contrast material injection.

The T2-weighted sequence based on the half-Fourier reconstruction technique, termed *half-Fourier RARE* (rapid acquisition and relaxation enhancement) or *single-shot fast spin-echo*, allows each image to be obtained in less than 1 second, minimizing artifacts caused by small bowel peristalsis.¹⁴ They produce high contrast between the lumen and bowel wall, providing excellent depiction of wall thickening and changes in the fold pattern.

Limitations of half-Fourier RARE include its sensitivity to intraluminal flow voids and the fact that it poorly depicts the mesentery because of k space filtering effects,^{10,14} which are related to the combination of a single-shot acquisition and

partial Fourier technique. The latter results in selective spatial filtering, leading to the loss of fine details of tissues that exhibit low to moderate T2 relaxation times. The coronal and axial balanced gradient-echo MR images that are obtained yield contrast that is intermediate relative to contrast on T1- and T2-weighted images.

Various acronyms are used to describe the balanced gradient-echo sequences, including fast imaging employing steady-state acquisition (FIESTA), true fast imaging with steady-state precession (FISP), and balanced steady-state free precession, depending on the manufacturer. These pulse sequences are particularly effective as a means of obtaining information about mural and extraintestinal abnormalities. The black boundary artifact encountered at fat-water interfaces with the balanced gradient-echo sequence can be clearly differentiated from abnormal bowel wall thickening because the fat-water interface is of low signal intensity, which contrasts with the moderate signal intensity of the thickened small bowel wall.

Two- or three-dimensional spoiled gradient-echo fat-saturated T1-weighted sequences can be used to acquire contrast-enhanced images. Because contrast-enhanced images acquired with 3D volumetric sequences provide better spatial resolution and allow multiplanar reconstruction, they are preferred with fully cooperative patients. When patients have difficulty in breath holding and remaining still, a 2D T1-weighted sequence, which is less susceptible to motion artifacts but has reduced spatial resolution, may be used instead of the 3D volumetric sequences. Gadolinium-based contrast material is administered by injecting 0.2 mmol/kg of body weight at a rate of 2 mL/sec, followed by a bolus injection of 20 mL of isotonic saline. Coronal gradient-echo fat-saturated T1-weighted sequences are obtained before and 30 and 70 seconds after the injection, followed by an axial sequence beginning 90 seconds after the injection, which covers the entire abdomen. The entire protocol for MR enterography takes 20 to 25 minutes.

Few studies have investigated the role of diffusion-weighted imaging for the detection of bowel inflammation in Crohn's disease. The apparent diffusion coefficient may facilitate quantitative analysis of disease activity. Visual assessment of diffusion-weighted images may provide greater accuracy, whereas calculation of the apparent diffusion coefficient may facilitate a quantitative analysis of disease activity.⁴⁹⁻⁵¹

Some authors have demonstrated that inflamed bowel segments have more restricted diffusion compared with normal

TABLE 40-1 Parameters for 1.5-T MR Small Bowel Imaging

Parameter	True FISP		T2-Weighted Half-Fourier RARE		T1-Weighted 3D Vibe	2D True FISP

VIBE, volumetric interpolated breath-hold examination.

bowel segments, and have further shown that diffusion-weighted imaging (DWI) is more sensitive than dynamic contrast-enhanced (DCE) MRI for actively inflamed terminal ileum; combining both techniques can potentially improve diagnostic specificity.⁴⁹ Other authors have reported a sensitivity, specificity, and accuracy of 86.0%, 81.4%, and 82.4%, respectively, for the detection of disease-active segments.⁵⁰ Another study demonstrated restricted diffusion in inflamed portions of the colon in patients with ulcerative colitis,⁵¹ one of which also showed that DWI had similar accuracy to contrast-enhanced sequences for detecting inflamed bowel. The outcomes of these studies suggest an evolving role for DWI in inflammatory bowel disease.

The ultrafast acquisition of the balanced steady-state free precession (SSFP) technique described earlier allows high temporal resolution imaging of the whole length and width of the abdomen in a coronal slice with subsecond repetition times during a single breath-hold. The resulting cine sequence can be used to evaluate small bowel peristalsis visually, and identify areas of altered motility, specifically focal areas of paralysis or hypomotility. Cine MR sequences have been found to detect more specific findings for Crohn's disease than standard MR enterography and identified significantly more patients with Crohn's disease than those identified on MR enterography alone.⁵² Moreover, cine MRI was a feasible approach for detecting a longitudinal ulcer in small bowel Crohn's disease, which appeared as asymmetric involvement or mesenteric rigidity with antimesenteric flexibility.⁵³ More recently, software methods have been developed to assess small bowel motility in an automated manner as well as analyzing the motility quantitatively,^{54,55} suggesting a role for quantified motility in assessing disease activity.

MRI of the small bowel can be performed with a 3-T system,⁵⁶ but the higher field strength requires modifications of the pulse sequences that are used at 1.5 T. Higher specific absorption rates because of the long acquisition time needed to obtain axial sections of the entire abdomen with a half-Fourier RARE sequence at 3 T are often a limiting factor. The use of parallel imaging techniques may help reduce the acquisition time and decrease the specific absorption rate, but such reductions are achieved at the expense of the signal-to-noise ratio. The use of FISP sequences is not always feasible at 3 T because of distortion artifacts. However, it is possible to obtain dynamic T1-weighted images at 3 T that have spatial resolution commensurate with that of T1-weighted images obtained at 1.5 T.

Image Interpretation

Initially, MR fluoroscopic sequences are used to assess the grade of distention of the small bowel and provide a panoramic view of the caliber and location of the jejunal and ileal loops. The images are displayed in the cine loop mode to visualize small bowel mobility.

The transit of the polyethylene glycol solution through the small bowel is considered normal when unimpeded flow of intraluminal solution from the duodenojejunal junction to the ascending colon is observed, with no evidence of transit delay or stenosis. Low-grade stenosis is diagnosed when contrast material reaches the site of obstruction without any delay and flows into the loop below the obstruction. In patients with a high-grade partial small bowel obstruction, the arrival of contrast material at the site of obstruction is delayed, and only a minimal amount flows into the collapsed loop beyond the

obstruction, thus making it difficult to define the fold pattern. A transition zone between the dilated bowel above and the narrowed bowel below marks the site of any obstruction. MR fluoroscopic pulse sequences yield useful information concerning the distensibility of narrowed areas, facilitate the differentiation of contractions from strictures in the evaluation of prestenotic dilation, evaluate small bowel mobility, and demonstrate findings similar to those seen at barium enema examinations, such as the morphology of the stenosis, which help differentiate among mucosal, submucosal, and extraparietal origins of disease.¹⁸

Balanced gradient-echo and T2-weighted images are examined to detect the presence of bowel wall thickening. Multiplanar projections can be obtained by alternating between axial and coronal acquisitions.

The main challenge in MR image interpretation is bowel underdistention, which may mimic or mask disease. When mural thickening is consistently observed on images from different sequences and planes, the likelihood of a correct diagnosis increases. A wall thickness more than 3 mm in a properly distended small bowel loop should be regarded as abnormal. The presence of perienteric or mesenteric abnormalities is evaluated; a fat-saturated T2-weighted study can help detect perienteric inflammation and penetration. Gadolinium-enhanced images are obtained to enable detection of any hyperenhancement of the bowel wall. In a narrowed segment, hyperenhancement can be used to differentiate contraction from mural disease. If the enhancement is identical to that of adjacent bowel loops in the same segment, it most likely represents underdistended contracted normal bowel. If there is more mucosal enhancement (mucosal hyperemia) or notably less submucosal enhancement (bowel wall edema), true disease should be suspected. Delayed images may also help distinguish transient contractions from wall thickening.

If hyperenhancement is seen in a bowel wall of normal thickness, it is necessary to differentiate between true disease and artifact. In these cases, it is important to compare the enhancement with that of other loops that are similarly distended, and with that of bowel loops within the same segment, because normal jejunum enhances more robustly than normal ileum.

The enhancement pattern of bowel loops can help differentiate between small bowel diseases. Homogeneous hyperenhancement (white) can be seen in ischemia, inflammatory bowel disease, adhesions, and occasionally in tumors. A hypoenhancing (gray) wall may be seen in inflammatory bowel disease and tumors. Mural stratification (the target pattern) is typically seen in active Crohn's disease.^{14,18}

Clinical Applications

CROHN'S DISEASE

The evaluation of chronic inflammatory bowel disease presents several problems. First, it is important to identify the presence of Crohn's disease and differentiate it from other small bowel diseases. Second, the number, length, and locations of the segments involved in each patient need to be determined. Third, if a stenosis is present, it needs to be classified as inflammatory or fibrous so that the patient can receive appropriate medical or surgical therapy.

Furthermore, if inflammatory activity is present, it is important to distinguish among mild, moderate, and severe disease

because medical management differs depending on the disease stage. Fourth, the presence of mesenteric complications, such as abscesses and fistulas, need to be assessed because their presence influences the choice of therapy.⁵⁷⁻⁵⁹

The visualization of early changes of Crohn's disease, such as ulcerations and subtle wall thickening, is highly dependent on the quality of luminal distention.^{1,2,18} High-resolution (thin section) true FISP and half-Fourier RARE images can depict early Crohn's disease changes; for example, an aphthous ulcer appears as a nidus of high signal intensity surrounded by a halo of moderate signal intensity (Fig. 40-2).^{35,58}

Barium contrast enteroclysis and capsule endoscopy are more accurate than MRI as a means of detecting subtle mucosal abnormalities.^{1,3,18} However, the clinical importance of a mucosal break or a few superficial aphthous lesions is not clear. There is evidence that suggests that up to 13% of healthy asymptomatic individuals may have mucosal breaks and other minor lesions of the small bowel at capsule endoscopy.¹³

Two types of ulcers are seen in Crohn's disease, superficial aphthoid ulcers and deep fissuring ulcers. Deep fissuring ulcers are more clinically significant. They penetrate the mucosa into the deeper layers of the bowel wall, resulting in submucosal inflammation and edema. On MRI, they appear as thin lines of

high signal intensity oriented longitudinally or transversally (fissure ulcers) within a thickened bowel wall (Fig. 40-3).

Sensitivity values for the detection of bowel ulceration in the literature range from 75% to 90%.^{17,21,42} MRI can also be used to detect minimal disease on the basis of mucosal enhancement of the bowel wall after intravenous injection of contrast medium¹⁸ (Fig. 40-4).

Segmental mural hyperenhancement is a nonspecific finding of early disease, whereas the presence of asymmetric mural enhancement and thickening is pathognomonic for Crohn's disease. The sensitivity and specificity values of MRI for the detection of Crohn's disease in the literature range from 88% to 98% and from 78% to 100%, respectively.^{16,17,19,21-23}

Cine sequences more accurately demonstrate the number of abnormal bowel segments than static MRI scans. Altered bowel motility is an early imaging sign of Crohn's disease and helps identify abnormal bowel segments with subtle signs of inflammation on static images.⁶⁰

The management of Crohn's disease continues to evolve medically and surgically, and MR enterography has the potential to affect diagnosis and management.⁶¹⁻⁷⁰ Classification of disease activity in Crohn's disease based solely on clinical and laboratory parameters has not been clinically reproducible.^{69,71}

Figure 40-2 MR enterography in 22-year-old patient with Crohn's disease. Coronal half-Fourier RARE sequence shows aphthoid ulcerations (arrow), each of which is seen as a nidus of high signal intensity (an ulcer crater) surrounded by a rim of moderate signal intensity. Capsule endoscopy and colonoscopy were used to confirm these findings.

Figure 40-3 MR enterography in 25-year-old patient with Crohn's disease. Coronal half-Fourier RARE sequence shows mucosal irregularity (arrows) as thin lines of high signal intensity oriented longitudinally or transversally (fissure ulcers) within a thickened ileal wall, which is consistent with diffuse ulcerations in Crohn's ileitis.

Figure 40-4 MR enterography in 36-year-old man with suspected Crohn's disease. Coronal contrast-enhanced T1-weighted fat-saturated VIBE image of terminal ileum shows uniform wall enhancement of terminal ileum with normal thickness (*long arrows*), a finding that indicates mild inflammatory changes. Note increased vascularity in the adjacent small bowel mesentery (*short arrows*).

Behavior of disease first referred to the indication for surgery—perforating or nonperforating disease.⁵⁹ These definitions have been expanded to nonsurgical situations, and disease activity has been categorized as primarily inflammatory, primarily fibrostenotic, or primarily penetrating, depending on the dominating feature at a given point in time.

To overcome the limitations of the subjective nature and poor reproducibility of the clinical inflammatory index,⁷¹ an imaging-based classification was proposed.⁶¹ Crohn's disease was classified into four broad groups: active inflammatory; perforating and fistulating; fibrostenotic; and reparative and regenerative subtypes. The subtype classification requires accurate information concerning the presence of ulceration, edema, spasm, stricture, fistula formation, and associated inflammatory mesenteric mass. Given its high accuracy for the detection of morphologic and functional abnormalities, MRI has the potential to offer reproducible and objective data to classify the patient's subtype of Crohn's disease correctly and plan and monitor patient therapy (Table 40-2).

Bowel wall thickening (usually ranging from 1 to 2 cm), is the most consistent feature of Crohn's disease on cross-sectional imaging.²³⁻²⁴ It can be found in the acute and chronic phases of disease.

TABLE
40-2

Correlation Between Typical Findings of Crohn's Disease Stages and Magnetic Resonance Pulse Sequences

Disease Stage	Balanced Gradient-Recalled Echo	Half-Fourier RARE	Contrast-Enhanced T1-Weighted
Active	Fold thickening, mural ulcers, mural thickening, comb sign, mesenteric lymph nodes	Fold thickening, mural ulcers, mural thickening, mural edema	Mucosal hyperemia, mural thickening, mural edema, comb sign, mesenteric lymph nodes
Fibrostenotic	Stricture	Stricture, mural fibrosis	Stricture, mural fibrosis
Penetrating	Deep fissuring ulcers, fistulas, abscesses	Deep fissuring ulcers, fistulas, abscess	Fistulas, abscess
Regenerative	Regenerative polyps, decreased luminal diameter	Regenerative polyps, decreased luminal diameter	Decreased luminal diameter

MR signs that indicate active Crohn's disease include mucosal hyperenhancement, mural stratification with a prominent vasa recta (comb sign), and mesenteric fat stranding (Fig. 40-5). Mural hyperenhancement correlates with inflammation at histologic examination and is the most sensitive imaging finding of active disease.⁷² Mucosal and serosal enhancement, combined with intervening submucosal edema, contribute to a stratified or layered appearance on contrast-enhanced fat-suppressed T1-weighted images. A blurred wall enhancement pattern on delayed phase images is strongly correlated with high-grade disease and is observed, above all, in patients with extremely active inflammation.⁶² Mucosal hyperenhancement on MR enterography has demonstrated good correlation with the Crohn's disease activity index and is the most sensitive finding in active disease, which significantly correlates with histologic findings. Several studies have reported MR enterography sensitivities for the detection of active inflammatory disease ranging from 73% to 90%.⁶²⁻⁶⁶

Submucosal edema in the small bowel produces increased signal intensity on T2-weighted images and is seen with active inflammation.⁶⁶ DWI can be useful to detect inflammation in small bowel Crohn's disease (Fig. 40-6).^{50,51}

Linear ulcers along the mesenteric border constitute one of the most important signs of small bowel Crohn's disease. The ulcers run parallel to the shortened, concave, or straightened and somewhat rigid mesenteric border. The adjacent mesentery is thickened and retracted, especially at its junction with the affected bowel segment. The rigidity of the mesenteric border is caused by transmural inflammation that extends from the linear ulcer into the mesentery. Another highly characteristic feature is the sparing of the relatively redundant antimesenteric border, which retains pliability and forms folds and sacculations. Deformity of bowel loops such as

Figure 40-5 MR enterography in 48-year-old man with active Crohn's disease. **A.** Coronal true FISP image shows extensive fibrofatty proliferation of mesentery (*short arrow*) associated with diseased ileal loops (*long arrows*). **B.** Coronal half-Fourier RARE sequence shows diseased ileal loops (*arrows*) but provides poor information concerning the mesentery. Coronal (**C**) and axial (**D**) contrast-enhanced fat-saturated T1-weighted VIBE images show stratified contrast enhancement with avid enhancement of mucosa relative to submucosal and muscular layers (*long arrow*) and layered appearance. Note the high signal intensity linear structure caused by increased vascularity (*short arrows*) close to the mesenteric border of the small bowel segment involved, the so-called comb sign and inflamed mesenteric nodes (*small arrow* in **D**). **E.** T2-weighted fat sat image shows increased signal intensity of the thickened wall, indicative of submucosal edema (*arrows*) with small fluid collection.

Figure 40-6 Terminal ileal Crohn's disease on diffusion weighted imaging. **A.** Axial contrast-enhanced fat-saturated T1-weighted VIBE image shows stratified contrast enhancement with avid enhancement (*arrows*). **B.** T2-weighted fat sat sequence in axial plane showing an increasing intestinal bowel thickness with edema (*arrows*). **C.** Axial DWI (*b* value = 800) showing hyperintensity within the ileal wall (*arrows*).

pseudodiverticulum formation caused by asymmetric involvement by longitudinal ulcers and ulcer scars is well demonstrated on axial and coronal images.

The fibrostenotic disease subtype is characterized by the presence of strictures that may progress to bowel obstruction. The stricture can be classified as functionally significant if the upstream bowel dilation is more than 3 cm in diameter. In the fibrostenotic subtype of the disease, low-level inhomogeneous mural enhancement is demonstrated, with no evidence of associated edema (Fig. 40-7).

On cine images, fibrotic strictures appear as aperistaltic bowel segments that often demonstrate fixed mural thickening and luminal narrowing. The thickened submucosa of a strictured, fibrotic bowel segment does not typically display increased signal intensity on T2-weighted images in the absence of active disease because of the lack of mural inflammation and edema.

Reparative or regenerative disease subtype reflects inactive Crohn's disease and may be associated with other subtypes of disease located in different bowel loops. It is characterized by mucosal atrophy and presence of regenerative polyps. A minimal decrease in luminal diameter can be seen but there is no mural edema or evidence of active inflammation (Fig. 40-8).

The MR enterography features of the fistula-forming and perforating disease subtype include the demonstration of deep fissuring ulcers and sinus tracts, fistulas, to adjacent bowel loops or other organs, the demonstration of an associated abscess, and extraintestinal involvement.

Adhesions are frequent in Crohn's disease findings and usually are considered as prefistulous lesions. They are

manifestations of serosal involvement and a clear sign of the transmural extension of the disease.

Sinus tracts and fistulas are demonstrated by the high signal intensity of their fluid content on true FISP and half-Fourier acquisition single-shot turbo spin-echo (HASTE) images (Fig. 40-9). The cumulative risk of developing fistulas, for patients with Crohn's disease is 33% after 10 years and 50% after 20 years, with perianal fistulas being the most common type.^{69,73,74} The imaging findings related to fistulas include bowel angulation associated with bowel wall contiguity and linear tracts between these bowel loops.

Multiplanar MR enterography is useful for the complete evaluation of sinus tracts (Fig. 40-10). Desmoplastic and/or fibrotic reactions in the mesentery around the fistula create a star appearance of the fistula. Inflamed fistulas can demonstrate intense contrast enhancement because of their hypervascularity and hyperemia.

Extraintestinal complications, such as mesenteric inflammation, abscesses, and involvement of adjacent viscera, can also be well depicted by MR enterography in patients with fistula-forming and perforating subtypes of Crohn's disease. These findings are of clinical importance and can be observed (using cross-sectional imaging techniques) in up to 50% of patients (fibrofatty proliferation) and 35% of patients (abscesses), respectively.^{10,11} Fibrofatty proliferation of the mesentery is the most common cause of bowel loop separation seen on small bowel studies in patients with Crohn's disease.^{2,3}

The fibrofatty proliferation is the results of perivascular inflammation with fibrosis and muscularis propria contraction.²⁷ The extent of fibrofatty proliferation and its

Figure 40-7 MR enterography in 39-year-old patient with long-standing fibrostenotic type of Crohn's disease. Coronal (A) and axial true FISP (B) images show low-signal-intensity wall thickening in several ileal loops (arrows), causing proximal obstruction. C. Axial contrast-enhanced fat-saturated T1-weighted VIBE image shows homogeneous hyperenhancement of bowel wall (arrows).

Figure 40-8 31-year-old man with fistulizing Crohn's disease subtype. **A.** Coronal true FISP image shows adherence between diseased distal ileal loops (arrow). **B.** Axial half-Fourier RARE image and axial contrast-enhanced, fat-saturated T1-weighted VIBE image (**C**) sequences showing a ileoileal fistula (arrow), with intense contrast enhancement because of their higher vascular flow and hyperemia, indicative of active inflammation. **D.** Axial true FISP image shows also desmoplastic and inflammatory reactions in the mesentery around the fistula, creating a stellar appearance (arrow). Multipplanar MR enterography is useful for a complete evaluation of the fistular tracts.

Figure 40-9 Crohn's disease fistula. Coronal true FISP sequence shows fistula tract between the terminal ileal and transverse colon (arrow).

Figure 40-10 Regenerative polyps on MR enterography. Coronal true FISP image shows mucosal atrophy and presence of regenerative polyps (arrows). A minimal decrease in luminal diameter can be seen, but there is no mural edema.

composition—mostly fatty or fibrotic—is best assessed with MR enterography using true FISP sequences.

Abscesses can be recognized by their fluid content and mural hypervascularity, and MR enterography can detect, localize, and indicate the cause of fluid collections (Fig. 40-11). Phlegmons show increased signal intensity as the thickened bowel wall on T2-weighted images. Sinus tracts are often associated with a phlegmon in the adjacent tissue.

SMALL BOWEL NEOPLASMS

The diagnosis of small bowel tumors, particularly early detection and differential diagnosis, is challenging.^{18,75} Although the spatial resolution of MRI is inferior to that of multidetector

computed tomography (MDCT), the main advantages of the former are the combination of good soft tissue contrast, detection of extraenteric abnormalities, and lack of radiation exposure, which allows repeated data acquisition for functional bowel evaluation (Fig. 40-12).⁷⁶⁻⁸³

Enteroclysis provides greater distention of the entire small bowel than enterography in patients suspected of having small bowel neoplasms because small polypoid masses that do not produce obstruction are more difficult to detect using oral contrast material distention.¹⁸

Moreover, MR enteroclysis delineates superficial changes more accurately than MR enterography,^{21,67} and the evaluation of endoluminal abnormalities is particularly important in the detection of early-stage small bowel neoplasms. MR enteroclysis

Figure 40-11 MR enterography in 45-year-old man with long-standing Crohn's disease and abscess formation. **A.** Axial T2-weighted half-Fourier RARE image shows high signal intensity edematous wall thickening of terminal ileum (*short arrow*). Note a hyperintense fluid collection (*long arrow*). **B.** Axial contrast-enhanced, T1-weighted, fat-saturated VIBE image shows marked enhancement of wall of the collection (*long arrow*). Note air bubbles in the cavity (*short arrow*). **C.** Axial DWI (b value = 800) showing restricted diffusion of the collection (*arrow*). These findings are consistent with an abscess.

Figure 40-12 MR enterography of jejunal gastrointestinal stromal tumor in 55-year-old patient with unexplained gastrointestinal bleeding. **A.** Coronal true FISP image shows lobulated mass that arises from a jejunal loop, with smooth borders and extraluminal growth (*arrow*), suggesting submucosal origin of the neoplasm. **B.** Coronal contrast-enhanced, fat-saturated, T1-weighted VIBE image shows homogeneous enhancement of the mass (*arrow*).

has yielded a 96.6% accuracy in the detection of small bowel neoplasms.^{67,75}

A recent study has shown that MR enterography is an accurate, well-tolerated, promising imaging modality to diagnose or exclude small bowel tumors in symptomatic patients with negative upper and lower endoscopy findings.⁷⁹ MR enterography can help triage patients to more invasive diagnostic methods.⁸²

MR enterography, which allows improved localization of small bowel polyps in patients with Peutz-Jeghers syndrome, is performed to identify larger lesions that should be resected at double-balloon enteroscopy or surgery.⁸³ It may also be helpful for excluding the presence of lesions in bowel segments not examined at endoscopy or surgery.

MR enteroclysis has proved to be more sensitive than CT enteroclysis for the detection of mucosal lesions of the small bowel⁷⁸ because of improved detection of segments with subtle abnormalities. These findings may be the result of the better soft tissue contrast afforded by MRI, which is required for tissue characterization and the detection of subtle areas of abnormality,⁷⁹⁻⁸¹ and of its functional capabilities. Another advantage of MRI over CT is that the enhanced soft tissue contrast produced by MRI may provide more information regarding the nature of mesenteric small bowel tumors, thereby allowing better characterization of small bowel tumors. In this regard, benign tumors such as hemangiomas are typically strongly hyperintense on T2-weighted MR images, whereas lipomas or tumors with a marked fat content are spontaneously hyperintense on T1-weighted MR scans.⁸¹ With few exceptions (e.g., lymphoma), thickening of a long segment of the small bowel is indicative of a benign condition. When perienteric fat stranding is seen adjacent to the thickened bowel segment, an inflammatory process should be suspected; when the perienteric fat adjacent to the thickened bowel segment has a normal appearance, an acute inflammatory condition is less likely.⁸⁰

CELIAC DISEASE

The sensitivity and specificity of serologic tests (e.g., transtissue glutaminase, antiendomysial antibodies) and of the histologic examination of biopsy specimens from the duodenum are high.

Therefore, MRI is not performed to help detect celiac disease. MRI can, however, provide morphologic information obtained noninvasively, such as fold pattern abnormalities and bowel dilation, as well as extraintestinal findings, such as mesenteric vascular congestion, lymphadenopathy, hyposplenism, and intussusception.⁸⁴

Small bowel MR findings in celiac disease reflect the underlying villous atrophy. A decrease in the number of jejunal folds and an increase in the number of ileal folds results in a jejuno-ileal fold pattern reversal, which is observed in 63% to 68% of patients with untreated celiac disease and may, consequently, be considered to be highly suggestive of celiac disease (Fig. 40-13).^{85,86} By demonstrating intraintestinal and extraintestinal features, MRI may lead to the diagnosis of celiac disease in adults with nonspecific gastrointestinal (GI) symptoms, which may subsequently be confirmed with the aid of jejunal biopsy and serologic tests.⁸⁶

Furthermore, MRI may be used for follow-up and detection of the complications of celiac disease, such as adenocarcinoma and lymphoma. Refractory celiac disease should be suspected in patients who do not respond well to a gluten-free diet. This condition warrants a more aggressive diagnostic pathway because the type II subtype is associated with high mortality caused, above all, by its association with ulcerative jejunitis and enteropathy-associated T-cell lymphoma (EATL).

Transient intussusception is more frequently found in patients with severe celiac disease (i.e., type 2 refractory celiac disease). When the intussusception is less than 3 cm long, occurs in the absence of a lead point tumor, and is not responsible for small bowel obstruction at MR enterography, the findings are consistent with transient, self-limiting small bowel intussusception.

MR enterography can effectively be used to detect lymphoma associated with celiac disease. An association has also been observed between certain mural characteristics and the presence of celiac disease, most notably that of a smooth marginal component, which is commonly observed in diseased segments in patients with celiac disease.⁸⁷ Because the expected findings are unlikely to emerge from within the bowel lumen, MR enterography, as opposed to enteroclysis, should be performed

Figure 40-13 MR enterography of celiac disease in 25-year-old woman. **A.** T2-weighted coronal HASTE image shows increased number of folds along ileal loops (arrows), with normal fold pattern in the jejunum. **B.** T2-weighted HASTE axial image shows jejunojejunal intussusception (arrow).

to detect complications in patients with known celiac disease and a poor response to medical therapy, as well as in those with recurrent or persistent symptoms despite gluten withdrawal.

BOWEL ISCHEMIA AND VASCULITIS

Bowel ischemia is a common but complex disorder with various primary causes and diverse clinical and imaging manifestations. Primary causes of insufficient blood flow to the intestine are numerous; these include thromboembolism, non-occlusive conditions (e.g., hypovolemia, hypotension, low cardiac output status, therapy with digoxin, α -adrenergic agonists, or β -receptor blocking agents), bowel obstructions, neoplasms, abdominal inflammatory conditions, chemotherapy- and radiation-induced enteropathies, and vasculitides. Regardless of the primary cause, the imaging findings of bowel ischemia are similar. MR enterography can depict the ischemic bowel segment and may also be helpful in determining the primary cause.⁸³

MR enterographic features of ischemia include thickening of the bowel wall, with or without the target sign, poor contrast enhancement of the bowel wall, and low-grade obstruction. Absence of enhancement or poor enhancement of the bowel wall appears to be the most specific finding. However, in some cases, the ischemic segment shows prolonged enhancement⁸³ because of abnormal perfusion (e.g., delayed return of venous blood with resultant slowing of the arterial supply or arteriospasm). Ischemia appears as marked enhancement of the bowel wall on gadolinium-enhanced T1-weighted fat-suppressed MRI scans, with persistent enhancement in the same region on late venous phase images obtained after gadolinium chelate injection.

INFECTIONS

Infectious processes are rarely detected initially at MR enterography. However, MRI may be useful for visualizing small bowel abnormalities that occur in the setting of chronic infectious diseases such as tuberculosis, as well as for monitoring such abnormalities during treatment.

Infectious diseases often cause a diffuse involvement of the jejunum and ileum, characterized by thickening of all jejunal wall layers with wall edema. The findings resolve completely after therapy (Fig. 40-14). Less common small bowel infections include giardiasis, tuberculosis, nontuberculous mycobacterial infection, and histoplasmosis. Such infections are more commonly seen in the setting of acquired immunodeficiency syndrome (AIDS). The associated MRI findings tend to be non-specific, such as bowel wall thickening, a stratified pattern of bowel enhancement, and enlargement of adjacent lymph nodes. GI tract tuberculosis tends to involve the ileocecal region; the cecum and ascending colon are usually involved to a greater degree than the terminal ileum. Characteristic MRI features of tuberculous enteritis include asymmetric thickening of the ileocecal valve and medial wall of the cecum, with deformation and contraction of the cecum and extension to the terminal ileum. Markedly enlarged adjacent lymph nodes with central areas of necrosis are often seen.^{80,83}

SMALL BOWEL OBSTRUCTION

MRI not only yields anatomic and functional information identical to that provided by conventional enteroclysis in cases of small bowel obstruction (SBO), but it also illustrates extraluminal features more clearly.^{88,89} MRI can also be used to

Figure 40-14 Bacterial enteritis in a 22-year-old man with AIDS. Coronal (A) and axial (B) HASTE images from MR enterography show thickened small bowel loops (arrows), with wall edema and fluid collection in the mesentery. C. Axial gadolinium-enhanced, T1-weighted fat-suppressed 3D image from MR enterography depicts enhancing thickened small bowel loops (arrows).

help detect bowel obstructions in the acute setting and differentiate malignant from benign forms in 92% of cases.⁸⁹ The use of MRI to evaluate possible high-grade SBO is useful in children and pregnant patients.

Features indicative of a malignant cause of obstruction include the presence of a mass, localized segmental mural thickening, and moderate or marked peritoneal thickening and enhancement. Benign intestinal obstruction is characterized by more generalized mural thickening and the absence of a true mass (Fig. 40-15).⁹⁰ Low-grade SBO may have numerous causes, although the most common are adhesions. Because MR enteroclysis can be used to monitor small bowel filling in real time without exposing the patient to ionizing radiation, it should be preferred over CT enteroclysis as a means of evaluating a low-grade obstruction.^{91,92}

Summary

MR enterography plays a pivotal role in the evaluation of the small bowel. MR enterography is rapidly becoming a first-line imaging modality for the diagnosis of inflammatory diseases and is gaining clinical acceptance for evaluation of small bowel disorders beyond Crohn's disease.

MR enterography allows evaluation of each bowel segment at multiple time points, which may facilitate differentiation of stricture from peristalsis as well as small bowel function.

MR enterography can be used to monitor response to powerful biologic therapies without the patient incurring

Figure 40-15 MR enterography of small bowel obstruction in 59-year-old patient. Axial half-Fourier RARE image shows a focal transition point at level, a jejunal loop with a so-called beak pattern (arrow), indicative of closed loop obstruction.

additional risk and may be a useful, noninvasive, radiation-free method of screening high-risk patients for subclinical intestinal inflammation. MR modalities, which help detect intraluminal and extraluminal morphologic and functional abnormalities without ionizing radiation, will keep radiology competitive in this era of improving endoscopic technology.

Crohn's Associated Adenocarcinoma, Neuroendocrine Tumor, and Lymphoma

Clinical Considerations

Crohn's disease is an idiopathic inflammatory disease that can affect any part of the gastrointestinal (GI) tract from the mouth to the anus. Patients with this disease have a genetic predilection to an abnormal immunologic response to environmental factors, including food, and gut flora leading to a chronic inflammatory response. The small bowel is the major site of involvement. With the exception of malignant neoplasms, Crohn's disease can be the most devastating disease to involve the GI tract. Its prevalence has increased, mostly in younger age groups, with a peak age between 15 and 25 years.¹⁻³ It has a worldwide distribution but is most common in northern Europe, North America, and Japan.⁴ Four studies have shown a bimodal distribution, with the first peak in the second or third decade of life and the second, smaller peak in the sixth or seventh decade. However, four other studies have shown a unimodal distribution, peaking in the second or third decade, and decreasing thereafter.⁵ The colonic predominance in older adults has led some to speculate that the second peak incidence in this cohort is caused by ischemia or diverticulitis. Both genders are equally affected, although some studies have shown a slight female predominance.⁵ A familial tendency has frequently been described.¹⁻³

The small bowel is commonly involved by Crohn's disease, with the terminal ileum the most common location. In a review

combining multiple population-based studies on the natural history of adult Crohn's disease, approximately one third of patients had ileitis, one third had colitis, and one third had ileocolitis.⁶ Isolated perianal disease occurs in 2% to 3%,⁷ but perianal or rectal fistulae are common in colonic or rectal disease (10% to 37%).⁶ Upper GI tract involvement is being recognized with increasing frequency but almost invariably occurs with small bowel or colonic disease. The gastric and duodenal manifestations of Crohn's disease are discussed in Chapter 30, and the colonic features of this disease are discussed in Chapter 58. Although the focus of this chapter is on Crohn's disease of the small bowel, there are differences in presentation from colonic disease. Patients with colonic Crohn's disease are more likely to present with blood loss, perianal disease, toxic colitis, and extraintestinal complications. Crohn's disease in the small bowel has a slightly better prognosis, although there are more likely to be complications such as abscesses, fistulae, and obstruction. Abdominal pain, mild diarrhea, weight loss, and pyrexia are common clinical findings. Other patients may present with a right lower quadrant mass, representing the diseased ileum or cecum. Delays of 3 to 4 years have been reported between the onset of often subtle symptoms and the diagnosis of Crohn's disease in the small bowel.⁷

Many factors contribute to the development of diarrhea in patients with Crohn's disease. An inflamed bowel mucosa causes increased secretion of fluid and electrolytes. Extensive terminal ileal disease or resection impairs bile salt reabsorption, leading to the malabsorption of fat and fat-soluble vitamins. Bacterial overgrowth secondary to strictures, fistulae to the colon, adhesions, aneurysmal dilation, or bypassed loops can also cause diarrhea. The combination of decreased food absorption and intermittent obstruction may lead to significant weight loss in these patients.^{7,8}

Classification and Therapy

Over the years, attempts have been made to classify Crohn's disease anatomically, clinically, and operatively. This has evolved from the International Working Party in 1991 to the Vienna classification in 1998, and finally to the Montreal revision of the Vienna classification in 2005.⁹

The Montreal revision classifies the disease into age of diagnosis, location, and disease behavior. Disease behavior is classified into nonstricturing, nonpenetrating (uncomplicated, active inflammatory alone), stricturing, and penetrating, with the addition of perianal disease as a modifier. It is the behavior subcategory that is of interest in regard to the radiographic manifestations. As a result of these morphologic subtypes, radiologists and even gastroenterologists have concluded that they are separate entities. The problem with this discrete approach is that the complex relationship between active inflammatory and stricturing disease and stricturing and penetrating disease has been forgotten or avoided. Crohn's disease

is a progressive process, starting with acute inflammation. It may be stopped or retarded with therapy; there may be mucosal healing. However, when it progresses, it often progresses to the fibrostenotic phase, with stricture formation. Active inflammation commonly coexists in the presence of stricture formation.^{10,11} There is also strong pathologic and clinical evidence that fistulae form in the face of fibrostenosis. Two pathologic series have shown that fistula formation without stricturing disease is uncommon to rare (4% to 7% of the time).^{12,13} Thus, if there is no stricture, penetrating disease (sinus tracts, fistulae, abscess, or free perforation) will be very unlikely. Because of the potential progression of disease from acute inflammation to fibrostenosis and then fistulization, it is important for the radiologist to think more broadly than using the Montreal and Vienna classifications, especially with computed tomography (CT) and magnetic resonance (MR) enterography. We are thus beginning to use the following terms—*active inflammatory disease, mixed active inflammatory and fibrostenotic disease, fibrostenotic disease, and inactive or quiescent disease with the addition of penetrating disease* (generally in the presence of mixed disease) based on radiographic findings (see later, “[Nomenclature for Computed Tomography and Magnetic Resonance Enterography Findings](#)”).

Medications useful for the active inflammatory subtype of Crohn's disease include 5-aminosalicylate-based drugs, corticosteroid-based drugs, and antibiotics (e.g., metronidazole, ciprofloxacin). Second-line medications are immunosuppressive agents such as azathioprine, 6-mercaptopurine, and methotrexate.^{14,15} Targeted monoclonal antibodies such as infliximab, which targets human tumor necrosis factor- β , and natalizumab, which targets β_4 integrin, a leukocyte adhesion molecule, have become available.¹⁵ These drugs are very expensive and have complications. This arsenal of medications has prompted the need for noninvasive, reproducible, and objective measurements of Crohn's disease activity, especially the distinction between active inflammatory disease from mixed fibrostenotic and active inflammatory disease with or without penetrating disease. Some centers of excellence would argue that penetrating disease can only be treated with surgery rather than medical therapy.

The fistulizing-perforating type requires antibiotics initially to treat the active infection. Monoclonal antibodies have proven effective in patients with perianal disease and enterocutaneous fistulae. However, internal fistulae (enteroenteric, enterocolic, enterovesicular, and complex internal fistulae) are much more difficult to treat medically.¹⁶ Percutaneous abscess drainage is a suitable means of treating Crohn's disease-related abscesses. The fibrostenotic subtype of Crohn's disease may need strictureplasty or bowel resection because small bowel obstruction is the major clinical manifestation of this type. The quiescent or reparative type of Crohn's disease may require maintenance medication.¹⁷

Diagnostic Tools

There are many examinations available for diagnosing, staging, and following Crohn's disease of the small bowel. These include ileocolonoscopy with direct inspection and biopsy of the terminal ileum, push enteroscopy to examine the proximal and mid small bowel, video capsule endoscopy, conventional small bowel follow-through, conventional enteroclysis, CT with (CTE) or without enterography or enteroclysis, MR enterography (MRE)

or enteroclysis, ultrasonography, and lately positron emission tomography (PET), PET/CT, and PET/MRI.^{18,19} These studies are used to do the following:

- Demonstrate the early changes of Crohn's disease.
- Depict the full extent of involvement and the possible presence of skip lesions if surgery is contemplated.
- Determine the cause of any clinical deterioration in previously stable patients with Crohn's disease.
- Distinguish between spasm (active inflammatory disease), mixed active and fibrostenotic disease, and fibrostenotic disease (stricture formation); increasingly used to dictate medical versus surgical therapy, especially with MR enterography.
- Investigate postoperative complications of Crohn's disease.
- Definitively rule out the presence of Crohn's disease in the small bowel, especially in patients with an indeterminate colitis.

ILEOCOLONOSCOPY AND VIDEO CAPSULE ENDOSCOPY

Ileocolonoscopy (Figs. 41-1 and 41-2) allows the accurate diagnosis of Crohn's disease of the colon and terminal ileum. It provides assessment of disease activity and consequences of inflammation visually and with guided biopsy, including strictures, mass lesions, bleeding, and the development of dysplasia or malignancy. In general, this examination is considered the gold standard for diagnosis.

Video capsule endoscopy is a new means of directly inspecting the entire length of the small bowel. It uses an ingested sealed capsule that measures 27 mm in length and 11 mm in width. The camera within the capsule, which also contains a light source, takes two photographs at eight times magnification every second and runs on electricity supplied by onboard batteries. During the typical small bowel examination, an average of about 55,000 photographs are taken. The capsule is propelled through the GI tract by peristalsis. The images are transmitted in radiofrequency signals to and stored on a recorder device placed in a belt worn by the patient throughout the day of the procedure. The capsule is disposable and is not recovered after the test. At the end of the study, the recorder device is retrieved and the images obtained are downloaded onto a computer. The computer generates a video that is then reviewed for relevant pathology.²⁰

Early studies have shown video capsule endoscopy (see Fig. 41-2B) to be the most sensitive means of diagnosing nonstricturing Crohn's disease.²¹⁻²⁶ However, the presence of a potentially obstructing stricture is a major contraindication for the use of capsule. Furthermore, many if not most of the studies that have shown the high sensitivity have not had corroborating reference standards. The studies that compared capsule with CT enterography-enteroclysis and/or MR enterography-enteroclysis have only shown that capsule is superior for disease more proximal to the terminal ileum, with no significant difference between the imaging studies and capsule in the terminal ileum.²⁷⁻²⁹ The only reference standard used to demonstrate the increased diagnostic efficacy of capsule over imaging has been the capsule findings. Even a recent four-center Danish trial, which showed that capsule is superior to CTE or MRE, only had the terminal ileum as a reference standard (5 of 93 had surgery); also, in this trial, a capsule examination was only performed after the enterography showed no stricture.³⁰ In this study, the

Figure 41-1 Early active inflammatory Crohn's diseases: Enlarged lymphoid follicles. **A.** Double-contrast barium enema examination with reflux into the terminal ileum shows prominent lymphoid follicles. This is a nonspecific finding that can be found in a variety of forms of infectious, inflammatory, immunologic, and neoplastic disease. **B.** Image from an ileocolonoscopy study shows multiple lymphoid follicles in this patient with early Crohn's disease.

superiority of capsule was for proximal disease, not the terminal ileum.

Capsule is well known to be highly sensitive but relatively low in specificity. In a comparison of standard small bowel examination, ileocolonoscopy, CTE, and capsule performed in Crohn's patients at the Mayo Clinic, the specificity of capsule was only 53% (sensitivity, 83%). In this study, the sensitivity and specificity of CTE and ileocolonoscopy were 82% and 89% and 74% and 100%, respectively.³¹

BARIUM CONTRAST EXAMINATIONS

In this new millennium, the barium–fluoroscopic barium examination of the small bowel for Crohn's disease has been largely supplanted by CTE and MRE. However, there are patients who have medical conditions that preclude the use of CTE or MRE with contrast enhancement (e.g., severe chronic kidney disease) who have known or suspected Crohn's disease. These patients must be evaluated with a barium examination using fluoroscopy.

There are two methods of examining the small bowel with barium using fluoroscopy—the standard small bowel series and enteroclysis. For accuracy, both require meticulous fluoroscopic technique using patient rotation and graded compression with a lead glove, inflatable paddle, or wooden spoon. Enteroclysis is available only in certain centers and requires intubation of the proximal small bowel via the nose or mouth. This is uncomfortable for most patients, and conscious sedation is used in some centers to improve patient tolerance.³²

As a general rule, the key radiographic finding in Crohn's disease is asymmetry. Radiologists usually think of asymmetry as skip disease in the z direction (see Figs. 41-1A, Fig. 41-2C,

and Fig. 41-6). However, the asymmetry of Crohn's is also in the xy direction (see Fig 41-2C). Crohn's disease always affects the mesenteric more than the antimesenteric border. The normal undulating fold pattern on the mesenteric border will become ulcerated, effaced, flattened, and foreshortened, whereas there is relative sparing of the antimesenteric border, giving rise to the pseudodiverticulosis sometimes associated with the disease (see Fig. 41-5). This classic feature is better portrayed with barium examinations, but can be seen with CT or MR enterography.

Marshak's ten principles of Crohn's disease are worth remembering because they assist the radiologist in detecting and characterizing disease.³³ Initially presented in 1973, these principles have generally held very true. The principles most helpful for the radiologist include principle 3 (the string sign is the most pathognomonic barium manifestation and does not represent fibrosis but spasm secondary to ulceration), principle 8 (following surgery, recurrence is common), and principle 9 (look for recurrence at anastomotic and stricture-plasty sites).

Early Active Radiographic Inflammatory Disease

The pathologic and radiologic findings correlate well in early Crohn's disease.³⁴⁻⁴⁰ The earliest histologic changes consist of hyperplasia of lymphoid tissue (see Fig. 41-1A) and obstructive lymphedema in the submucosa. Because the submucosa extends into the core of mucosal folds, the folds may thicken at this stage in a smooth, symmetric manner. However, in general, symmetric fold thickening in Crohn's disease is an uncommon finding, and is identified only early in the disease. When the disease advances, the folds become much more asymmetrically thickened, giving a macronodular polygonal appearance; the

Figure 41-2 Early active inflammatory Crohn's disease: Aphthoid ulcerations. **A.** Image of the terminal ileum obtained during ileocolonoscopy demonstrates an aphthoid ulcer (arrow). **B.** Small bowel video capsule study shows two aphthoid ulcerations (arrows) in the distal ileum. **C.** Double-contrast image of the terminal ileum shows multiple aphthoid ulcerations (arrows).

macronodules vary in size (at this point, the main differential is lymphoma; see later).

Hyperplasia of lymphoid follicles (see Fig. 41-1) in the lamina propria can be associated with shallow, 1- to 3-mm mucosal erosions surrounded by a small halo of edema, also known as aphthoid ulcers (see Fig. 41-2).⁴¹⁻⁴⁴

Intermediate Radiographic Active Inflammatory Disease

As the disease gradually extends transmurally, further changes take place in the mucosa and submucosa. Progressive submucosal edema may cause the base of the folds to widen until some folds are partially or completely obliterated or effaced, especially on the mesenteric side. This process is similar to the thumbprinting that occurs in patients with bowel ischemia. In patients with ischemia, however, the fold abnormalities change

over a period of days to weeks, whereas in patients with Crohn's disease, the fold abnormalities persist and are usually associated with changes of more advanced Crohn's disease elsewhere in the small bowel. The mucosal inflammatory infiltrate tends to vary focally in intensity. This infiltrate, together with patchy submucosal fibrosis, leads to a distortion and interruption of folds.⁴¹⁻⁴⁵ The fold pattern in this stage can be described as macronodular (>1 cm), with the nodules asymmetric in size, location, and appearance.

Some aphthoid ulcers may enlarge and deepen, producing a stellate or rose thorn appearance. Other aphthoid ulcers may fuse with adjacent ulcers, producing crescentic or linear shapes. A typical finding is that of a long linear ulcer on the mesenteric border, which may be accentuated by a parallel radiolucency caused by fusion of thickened, transaxially oriented folds. The mesenteric border ulcer is associated with thickening, sclerosis,

and retraction of the adjacent mesentery and of the straightened mesenteric border of the involved bowel. At the same time, the unaffected, or relatively unaffected, redundant antimesenteric border becomes pleated, scalloped, or sacculated, giving a pseudodiverticular-like pattern (distinct from the pseudodiverticular pattern present in scleroderma, in which the outpouchings are much closer together because of the foreshortening of the bowel).

An inflammatory cellular infiltrate with focally pronounced edema and granulation tissue can give rise to localized mucosal elevations or inflammatory polyps. These lesions are common in the colon but infrequent in the small bowel. Inflammatory pseudopolyps usually occur in small numbers in an area of mucosa that is denuded of folds. Occasionally, a bowel segment contains many inflammatory pseudopolyps (≤ 1 cm in

diameter), separated from one another by curving lines of barium occupying the crevices between the elevations. When seen in profile, the polyps appear as notches demarcated by protrusions of barium. The diameter of these bowel segments is not reduced. This is called the nodular pattern of Crohn's disease to underscore its essential difference from the ulceronodular, or cobblestone, pattern of advanced, fissuring, ulcer-related Crohn's disease (Fig. 41-3).⁴¹⁻⁴⁵

Advanced Radiographic Active Inflammatory Disease

In advanced Crohn's disease, the process has extended transmurally to the serosa and beyond. Deep linear clefts of ulceration, or fissures, are typical of this stage of the disease (Fig. 41-4). Islands of surviving mucosa surrounded by extensive ulceration

Figure 41-3 Active inflammatory Crohn's disease: Cobblestone mucosa. A, B. Multiple transverse and longitudinal ulcerations of the terminal ileum are identified on conventional small bowel examinations performed in these two patients with Crohn's disease. C. Specimen showing cobblestone mucosa.

Figure 41-4 Deep ulcerations of fistulizing-perforating Crohn's disease. **A.** Specimen radiograph shows two deep ulcerations (arrows) penetrating into the fat of the small bowel mesentery. **B.** A fissuring ulcer (arrow) is identified on this pathologic image.

give the appearance of elevations above the ulcerated background. These islands of mucosa are therefore known as pseudopolyps. The deep fissures characteristic of this advanced stage may be manifested by a combination of axial and transaxial fissuring, which separates the pseudopolyps from one another. This finding is always associated with luminal narrowing; it is

referred to as the ulceronodular or cobblestone pattern of advanced Crohn's disease (see Fig. 41-3).⁴¹⁻⁴⁵ This pattern should not be confused with the nodular pattern of less advanced Crohn's disease.

Changes associated with linear mesenteric ulceration advance in a caudad direction as the disease progresses. Antimesenteric redundancy of the opposite bowel wall gradually disappears as it is incorporated in the transaxial extension of ulcerated Crohn's disease (Fig. 41-5). The bowel wall is now thickened by a combination of fibrosis and inflammatory infiltrate. Another feature of transmural disease is the so-called fat wrapping that occurs as the hypertrophied subperitoneum is tethered toward the bowel wall by mesenteric perivascular fibrosis.⁴⁵

Quiescent or Inactive Disease

Very little has been written about the barium findings of quiescent disease. Presumably, the mucosa is normal in these patients. Thus, the fold pattern should be normal.

Fibrostenotic Disease

The strictures of small bowel Crohn's disease (Figs. 41-6 and 41-7) are caused by collagen deposition, predominantly in the submucosa. It is important to differentiate fibrostenotic strictures from the luminal narrowing that can result from spasm. The classic string sign of Crohn's is primarily caused by spasm in segments of active inflammatory disease. Fluoroscopically, the lumen, coated with barium, appears initially narrowed, with no or only mild upstream dilation. Then, when a peristaltic wave propels the barium through the lumen, the lumen expands to a near-normal caliber. A fibrostenotic predominant stricture will not change its caliber with peristalsis, and the upstream, nonaffected lumen will be dilated, regardless of the state of peristalsis. It should be noted that in many if not most cases of the string sign, the lumen of the affected bowel never fully distends, and there is often some degree of upstream ballooning or dilation during peristalsis. This suggests that more than spasm is occurring in the affected segment (Crohn's is a progressive process; at sites of active disease, there is often active proliferation of smooth muscle and collagen that restricts compliance).

These strictures are an important cause of small bowel obstruction, often necessitating surgery. Strictures or stricture-like findings are reported in 21% of patients with small bowel Crohn's disease.^{7,44} MDCT, magnetic resonance imaging (MRI), CT enterography, CT enteroclysis, and MR enteroclysis are valuable techniques for differentiating fibrotic strictures from lumen narrowing by spasm or active ulcerated stenotic disease. It is important to note that active inflammation is present in many, if not most, fibrostenotic strictures (see later). Obstruction by a fibrous stricture may require surgery; whenever possible, it should consist of strictureplasty to avoid bowel resection.⁴⁵ Some patients with Crohn's disease may develop high-grade small bowel obstruction; this complication is reliably documented by CT and MR.

Other patients with Crohn's disease may have multiple strictures, representing advanced skip lesions. Stasis related to strictures can be associated with bacterial overgrowth. This is especially true in patients who develop aneurysmal dilation of the small bowel (see Fig. 41-7), usually between two strictures. Strictures are generally well shown by barium study.

Resection of bowel in patients with Crohn's disease is followed by a high frequency (85%) of disease recurrence.

Figure 41-5 Sacculations in Crohn's disease. **A.** There is straightening of the mesenteric border (arrows) of the terminal ileum because of fibrofatty proliferation of the mesentery. **B.** Multiple segments of small bowel show straightening and shortening of the mesenteric border (white arrows) with a redundant antimesenteric border forming sacculations (yellow arrows).

Recurrent inflammation has been detected within 8 days of surgery, provided that exposure to the fecal stream had been reestablished. Multiple resections have made Crohn's disease of the small bowel a major cause of the short bowel syndrome.^{7,44}

Fistulizing or Penetrating Disease

Fistulizing or penetrating disease is manifest by sinus tracts, fistulae, abscess, and uncommonly free perforation. Abscesses develop in some 20% of patients with Crohn's disease, and most can be treated with percutaneous drainage.⁴ Inflammatory lesions may remain closely related to a diseased segment of bowel or may extend beyond the bowel, occasionally into the psoas muscle. In some cases, barium may enter an abscess cavity, a collection of tracts, or multiple small spaces within an inflammatory mass. However, CT, ultrasonography, and MRI are preferred diagnostic methods for evaluating abscesses in patients with Crohn's disease.

Fistulae are abnormal communications between two epithelial surfaces or an epithelial surface and the skin, which occur in 6% to 33% of patients with Crohn's disease.⁷ Fistulae occur in the presence of, and likely as a result of, stricture formation (fistulae are only rarely found in isolation, only 4% to 7% of the time; Fig. 41-8). Ileocecal, ileosigmoid, and enteroenteric fistulae are the most common and are often multiple. An enterocolic fistula may lead to bacterial overgrowth and is one of the causes of malabsorption associated with Crohn's disease.

Enterocutaneous fistulae can be well shown by barium studies, CT, and MRI.

Because the attachment of the transverse mesocolon crosses the mid-descending duodenum, Crohn's-related fistulae between the transverse colon and duodenum are not unusual. Recurrent Crohn's disease in the neoterminal ileum after ileotransverse colonic anastomosis may be associated with such a fistula. Ileosigmoid fistulae are encountered more often. These may serve a useful purpose by bypassing strictures in the ileocecal area. In most cases, the entry site of these fistulae into the sigmoid colon shows only nonspecific inflammatory changes. If surgery is contemplated, it is usually adequate to resect the diseased ileum and stricture, leaving the sigmoid colon intact.⁷

Disease Activity as Assessed by Barium

In the 1970s, the National Cooperative Crohn's Disease Study attempted to determine whether barium examinations could accurately assess response to therapy and whether barium findings correlated with clinical response, as judged by the Crohn's Disease Activity Index (CDAI).⁴⁶ Patients were divided into those with active, symptomatic disease (CDAI > 150; $n = 295$) and patients with disease that had been active, but was now quiescent (CDAI < 150; $n = 274$). The investigators concluded that the findings on barium examination did not correlate with clinical symptoms or response. In general, there was little improvement of barium findings during the study; only patients

Figure 41-6 Fibrostenotic Crohn's disease. These four patients demonstrate the string sign of Crohn's disease with narrowing and rigidity of the involved segments because of cicatrizing Crohn's disease. **A.** The terminal ileum is narrowed (arrows) and there is minimal proximal dilation. **B.** There is a sacculum (arrow) identified along the antimesenteric border of this very narrowed ileum. **C.** A segment of marked luminal narrowing (arrows) is identified in the distal jejunum. **D.** Specimen radiograph shows narrowing of the lumen of the terminal ileum (white arrow) associated with mural thickening (red arrows). Note the creeping fat (yellow arrows) on the mesenteric side of the distal ileum. **E.** Recurrent, stricturing Crohn's disease is evident on both sides of the ileocolic anastomosis (arrow).

Figure 41-7 Aneurysmal dilation of fibrostenotic small bowel in Crohn's disease. **A.** There is segmental marked dilation (red arrow) of a segment of the terminal ileum caused by a distal stricture (white arrow). **B.** There is a long segment of aneurysmal dilation (red arrow) of distal ileum located between two strictures.

treated for longer than 6 months with prednisone showed a statistically significant improvement in findings.

ULTRASOUND

Ultrasound has been increasingly used to assess Crohn's disease, especially in the pediatric population.⁴⁷ The examination

requires meticulous, systematic scanning of all parts of the bowel, using graded compression and a high-frequency transducer after the administration of oral contrast. Recently, investigations have shown the added benefit of contrast-enhanced ultrasound in assessing Crohn's disease, especially in differentiating fibrosis from active inflammation.⁴⁸ Mural thickening (Fig. 41-9) is the most common abnormality seen in patients with Crohn's disease of the small bowel.⁴⁹⁻⁶⁷ It is typically concentric, and the mural echogenicity depends on the degree of inflammatory infiltration and fibrosis. In early acute disease, mural stratification is retained. With long-standing disease, a target or pseudokidney appearance may be identified. In patients with burned out, long-standing disease, fat deposition in the submucosa may be present.

Actively inflamed gut appears rigid and fixed, with decreased or absent peristalsis.⁴⁹⁻⁶⁷ Color Doppler imaging typically shows hyperemia. Findings on spectral Doppler analysis include increased superior mesenteric and/or inferior mesenteric artery blood flow, increased pulsatility index, decreased resistive index, and increased portal vein velocity.⁴⁹⁻⁶⁷ Increased systolic and diastolic flow through the superior mesenteric artery may also be seen, attesting to disease activity. Creeping fat of the mesentery manifests as a uniform echogenic halo around the mesenteric border of the encased gut. As with barium study, MDCT, and MRI, this abnormal fat causes separation of bowel loops.

Prominent lymph nodes are seen in most patients with the active inflammatory phase of Crohn's disease. These perienteric lymph nodes, which are located in the subperitoneal space of the small bowel mesentery, present as focal hypoechoic masses that are spherical and have lost their normal echogenic streak emanating from the nodal hilum. These nodes are typically hyperemic, moderate in size, and tender. Abnormal lymph nodes are not commonly seen in quiescent Crohn's disease.⁴⁹⁻⁶⁷

Crohn's disease strictures show mural thickening of the gut, with the luminal surfaces of the involved segments in apposition (Fig. 41-10). The lumen may appear as a narrow, linear, echogenic central region within the thickened segment of small bowel. Dilated hyperperistaltic segments can be seen proximal to the strictured segments. Aneurysmal dilation and sacculation may be seen proximal to the involved segments.

Fistula appear as linear bands of varying echogenicity (Fig. 41-11), extending from the gut to the bladder, another segment of bowel, or bladder. Gas within the fistula will appear echogenic and may show the so-called ring-down artifact. An empty or partially closed tract will appear as a hypoechoic segment of bowel or bladder. Abscesses on ultrasound manifest as a fluid-filled or complex mass, which may contain gas.⁴⁹⁻⁶⁷

Recently, in an animal model, ultrasound elastography-derived shear wave velocity was found to help distinguish acutely inflamed from fibrotic bowel.⁶⁸ Much work needs to be performed to determine whether this technique can distinguish mixed fibrostenotic and active inflammatory disease from pure active inflammatory disease or fibrostenotic disease.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (see Chapter 40) has become a well-established technique in evaluating patients with known or suspected Crohn's disease by virtue of its ability to help confirm the diagnosis; localize lesions; assess their severity, extent, and inflammatory activity; and identify extraintestinal

Figure 41-8 Fistulizing-perforating Crohn's disease. **A.** Multiple ileocolic and ileoileal fistulae are shown on this small bowel series. **B.** Specimen radiograph shows an ileoileal fistula (yellow arrow). Note the cobblestone mucosa and deep ulcerations (red arrow) associated with mural thickening. **C.** Fistulae between the proximal small bowel and colon (arrow) are demonstrated on this radiograph.

complications that may require surgical intervention.⁶⁹⁻⁸⁸ MR enteroclysis is an emerging diagnostic tool that combines the advantages of conventional enteroclysis and MRI. However, MR enterography (MRE) is the most practical method of evaluating patients with Crohn's disease.

MRE has two major advantages over CTE. No ionizing radiation is used and, as a result, multiple pulse sequences with and without contrast enhancement can be performed. Static imaging can help identify wall edema and lymphatic distention, and contrast-enhanced imaging can be performed long after the injection has been given, potentially allowing for further characterization. The major disadvantage is a long examination time, requiring relatively long breath holding. Furthermore, magnet time is at a premium in many institutions and is used for many other disease states. Bowel motion remains a problem; glucagon and hyoscyamine (Levsin) are the only antiperistaltic agents approved in the United States (Buscopan or hyoscine butylbromide is an excellent agent but only approved in countries other than the United States). Finally, spatial resolution, even with 3-T magnets, does not approach the resolution of

MDCT with its near-isotropic imaging. Nevertheless, MRE is equivalent to CTE for the evaluation of Crohn's disease.⁸⁹⁻⁹²

Adequate distention of the bowel lumen is ideal in MRE because collapsed bowel loops can potentially hide lesions or mimic pathology. However, in general, the small bowel affected by Crohn's disease can almost always be detected unless there is significant bowel motion or no distention of a large amount of small bowel. Different methods have been used to achieve adequate distention. MR enteroclysis provides distention of the entire small bowel, visualizes mucosal abnormalities, and can show functional information about small bowel mobility.

Regardless of the pulse sequence, it is important to obtain imaging in orthogonal planes, often axial and coronal. These planes should be obtained in all patients on static and post-contrast scans. As with CTE, disease presence, strictures, and especially fistulae and sinus tracts are best elucidated with orthogonal imaging.

Many T2-weighted pulse sequences are available on modern scanners. New, fast, T2-weighted spin-echo sequences can be obtained in a single breath-hold. These include T2-weighted,

Figure 41-9 Crohn's disease: Sonographic features. **A.** Mural thickening is the sonographic hallmark of Crohn's disease. **B.** In acute disease, mural stratification is maintained. Yellow arrow, mucosa-muscularis mucosae; white arrow, submucosa; red arrow, muscularis mucosae. **C.** In chronic Crohn's disease, mural stratification is lost. **D.** The density of vessels seen on color flow Doppler ultrasound correlates with the degree of disease activity. (Courtesy Dr. Pierre-Jean Valette, Lyons, France.)

half-Fourier rapid acquisition with relaxation enhancement (RARE), turbo spin-echo (TSE), fast spin-echo (FSE), half-Fourier acquisition single-shot turbo spin-echo (HASTE), single-shot turbo spin-echo (SSTSE), EXPRESS, and the newest sequence, called BLADE, which uses periodically rotated overlapping parallel lines with enhanced reconstruction (PROPELLER). These T2-weighted sequences are obtained with and without fat saturation. Fat saturation helps identify and characterize increased T2 signal in abnormal loops of bowel (increased T2 signal in the wall can result from increased fluid from edema or lymphatic distention or from fat deposition). T1-weighted, gadolinium-enhanced, spoiled gradient-echo (SGE) sequences are also important in evaluating the location, extent, and severity of Crohn's disease.⁶⁹⁻⁸⁸ T1-weighted gadolinium-enhanced MRI has been the most investigated pulse sequence in Crohn's disease. A variety of 2D and 3D techniques are available; the most common use a fast, 3D, fat

saturated gradient-echo sequence acquired in a single breath-hold lasting 15 to 20 seconds. These sequences have a variety of names, such as VIBE, FAME, THRIVE, and 3D QUICK.⁶⁹⁻⁸⁸ T1 acquisition in regard to contrast enhancement varies, with acquisition commonly at 30, 60, and 90 seconds postinjection start. More delayed imaging of up to 8 minutes postcontrast may be helpful.¹⁰

Multiple coronal, true fast imaging with steady-state precession (FISP), cine motility sequences have been reported to differentiate between a high-grade and low-grade partial small bowel obstruction. These sequences give an MR "fluoroscopic" depiction of peristalsis above a stricture, showing the progressive dilation of bowel proximal to the stricture. Some believe that static imaging may not be able to make this distinction. However, in our experience, most significant strictures (predominantly fibrostenotic) demonstrated dilated loops of small bowel (>3 cm) proximally.

Figure 41-10 Fibrostenosing Crohn's disease: Sonographic features. Marked thickening of a segment of ileum (yellow arrows) is identified, causing dilation of the proximal small bowel (red arrow). (Courtesy of Dr. Pierre-Jean Valette, Lyons, France.)

Recently, in an animal model of Crohn's disease, magnetization transfer helped detect fibrosis.⁹³

COMPUTED TOMOGRAPHY

There are three major CT techniques (see Chapter 38) used for the evaluation of Crohn's disease of the small bowel—conventional positive intraluminal contrast studies, CT enterography (CTE), and CT enteroclysis.⁹⁴⁻¹⁰⁶ Conventional CT using positive intraluminal contrast agents is generally reserved for postoperative patients in whom a bowel leak is suspected. In a patient with an acute exacerbation of symptoms, one might argue that identifying an abscess is the most important question. Thus, conventional CT with positive oral agents should be used. However, many patients with acute symptoms do not have an abscess but have exacerbation of the disease, obstruction or progressive stricture formation with or without fistulization. We have found that CT enterography, even in these acutely ill patients, can confidently distinguish an abscess using neutral oral contrast agents. CT enteroclysis is a rarely used technique and is reserved for those institutions in which it is performed routinely. Finally, the assessment of mural enhancement is hindered by the presence of positive

Figure 41-11 Fistulizing-perforating subtype Crohn's disease: Deep ulcerations. An affected segment scanned longitudinally (A) and axially (B) shows mural thickening with deep ulcerations (arrows) and lumen stenosis. C. A fistula (red arrow) is seen extending from a diseased segment of the ileum (white arrow) to a small abscess cavity (yellow arrow). (Courtesy of Dr. Pierre-Jean Valette, Lyons, France.)

intraluminal contrast because this contrast obscures inner wall hyperenhancement.

CT enterography uses MDCT with a narrow section thickness and reconstruction interval, vis-à-vis (IV) contrast material, and large volumes of neutral contrast agent to distend the lumen in an effort to improve the detection of small bowel inflammation and extracolonic complications. CT can be performed during the enteric phase (45 seconds after injection) and portal venous phase (70 seconds after injection). Regardless of the technique used, there is no significant difference in detecting Crohn's disease.¹⁰⁷ Jejunal attenuation is greater than ileal attenuation, and collapsed bowel loops demonstrate greater attenuation than distended bowel loops.¹⁰⁸ CT enteroclysis uses contrast material infused through a nasojejunal tube. Both positive (dilute barium) and neutral contrast (water, methylcellulose, VoLumen) agents may be administered. CT enteroclysis uses the same technique as standard fluoroscopic enteroclysis, except that imaging is performed with contrast-enhanced MDCT, as in CT enterography.³² All MDCT datasets should be reconstructed in at least two planes, typically axial and coronal. Occasionally, sagittal or oblique planes are helpful in identifying fistulae.

Every effort should be made to limit radiation exposure in patients, especially if they have had multiple CT scans in the past. Several studies have shown that some Crohn's patients can receive large cumulative doses (>100 mSv) over the course of their disease, and often are examined with CT two to three times a year.¹⁰⁹⁻¹¹² In one series, encompassing a 15-year period, the mean ionizing radiation dose was 36.1 mSv. Over the entire study period, there was an increasing use of CT, and although CT accounted for only 16.2% of all imaging studies, it accounted for 77.2% of the radiation dose. Also, in this study, the total ionizing radiation exceeded 75 mSv in 15.5% of patients. Patients who receive higher doses have onset of disease before 17 years of age, have upper GI tract or penetrating disease, require IV steroids or infliximab, or have had multiple surgeries.¹⁰⁹ There is recent evidence that radiation exposure from CT scans in children results in an increased risk of brain tumors and leukemia.^{113,114} Most pediatric centers almost exclusively use MRE or ultrasound as a means of evaluating their patients.

Efforts to reduce the dose from MDCT are ongoing and include alterations in kVp and mAs in relation to body habitus, weight, body mass index (BMI), and altering the scan pitch, as well as applying new reconstruction techniques, generally termed *iterative reconstruction*, to initial lower dose images. Dose reductions from a CT scan are typically 15 to 20 mGy but can successfully be reduced to less than 10 mGy, and even below 5 mGy, have been achieved. However, the most substantial reductions in dose have been in patients who weigh less than 160 pounds. It remains to be seen whether sub-mSv imaging is possible without data loss. Crohn's disease identification is a high-contrast issue with CT (i.e., identifying a process with a higher attenuation compared with background). To date, low-contrast objects (an object of lower attenuation compared with background) are lost with lower dose MDCT,¹¹⁵ even with any of the known iterative reconstruction techniques, including model-based iterative reconstruction.¹¹⁶⁻¹¹⁸ To achieve a substantial reduction in dose from CT, radiologists may have to accept a lower sensitivity in detecting low-attenuation lesions in the liver, which are the low-contrast entities that occur most frequently in a patient population.

The most effective strategy for reducing ionizing radiation exposure in patients with Crohn's disease is to shift imaging to

MRE from CTE. Our strategy is first to perform CTE on all patients with Crohn's disease if they have not had one performed. This serves as the baseline examination, establishing the location and extent of disease. The study is fast, the spatial resolution is superb, and there is little to no bowel motion artifact. We favor CTE or MRE as the initial study because bowel motion remains a problem for MRE in the United States. Furthermore, the spatial resolution of MRE is still not equivalent to that of CTE. As a result, the risk of missing disease on an initial MRE image is relatively high. However, every other examination, except for patients who are acutely ill or perioperative, should be MRE. Acutely ill patients should be examined with CTE, especially if abscess detection and potential drainage is relatively likely. Once detected, the abscess can be rapidly drained using CT guidance. Postoperative patients should be examined after the ingestion of positive oral contrast medium and the administration of rectal contrast medium if there is a colonic anastomosis, because a leak may be present.

Nomenclature for CT and MR Enterography Findings

In an effort to measure the impact of CTE and MRE in the care of Crohn's patients, interested radiologists in the Abdominal Radiology Society (ARS), Crohn's Disease-Focused Panel are in the process of developing a nomenclature to describe the findings of Crohn's disease and how to interpret those findings. Tables 41-1 and 41-2 summarize this work, which should be considered a work in progress. The ultimate goal is to have international input and approval from radiologic, gastroenterologic and surgical societies. The purpose of a common nomenclature is to define and standardize the terms used to describe the findings and the conclusions that can be drawn from those findings. Ultimately, these terms and conclusions will be essential in measuring outcomes in regard to treatment and the impact of imaging on predicting treatment. These terms will be used here in the subsequent discussion of the findings of MRE and CTE.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE ENTEROGRAPHY FINDINGS OF SMALL BOWEL CROHN'S DISEASE

Both CTE and MRE identify the transmural, extramural, and mesenteric manifestations of small bowel Crohn's disease.^{119,120} Historically, investigators have described findings as mucosal, submucosal, serosal, or extramural-mesenteric. However, in many cases, the mucosa may be entirely destroyed, replaced by acute and chronic inflammatory cells. Furthermore, the precise anatomic location of the finding may not actually be known. Therefore, we think it best to avoid the use of these specific terms and prefer to use terms that are more generic and descriptive, rather than anatomic (see Table 41-1). Finally, because the findings on CTE and MRE are similar or identical, we will combine the discussion into one section.

Wall Findings

Hyperenhancement. One of the most consistent MRE/CTE findings is wall hyperenhancement. This is defined as increased signal intensity or attenuation on contrast-enhanced scans in a noncontracted segment of bowel. Comparison with adjacent or nearby small bowel segments is helpful in making this

TABLE
41-1

Abdominal Radiology Society Nomenclature for Computed Tomography and Magnetic Resonance Enterography Findings in Small Bowel Crohn's Disease (Work in Progress)

Findings	Description
WALL FINDINGS	
WALL HYPERENHANCEMENT	Increased attenuation and signal intensity on contrast-enhanced scan in noncontracted segment; compare with nearby small bowel segments.
Stratified (bilaminar or trilaminar)	Inner wall hyperenhancement or halo; no clinically significant difference between the two patterns
Homogeneous	Transmural hyperenhancement
Normal	
Asymmetric	Asymmetric or patchy hyperenhancement, often along mesenteric border with relative sparing along the antimesenteric border
WALL THICKENING	
• Mild	3-4 mm
• Moderate	5-7 mm
• Severe	>7 mm
Intramural edema	Hyperintense T2 signal; only on MRE (preferably fat suppressed); cannot comment on CTE
LUMINAL NARROWING	
STRICTURE	Narrowed diameter in a noncollapsed loop, with or without mural hyperenhancement
UPSTREAM DILATION	Luminal narrowing + upstream dilation (see below)
	Bowel lumen >3 cm, unequivocal segmental dilation of small bowel proximal to narrowed segment or small bowel feces sign above narrowed segment
• Mild	<4 cm
• Moderate	4-5.9 cm
• Severe	>6 cm
Ulcer	Wall defect that does not extend outside bowel wall in a thickened wall
Sinus tract	Wall defect that extends outside lumen but not to adjacent organs (usually accompanied by angulation and fixation of adjacent bowel and/or tethering of bowel or urinary bladder)
Simple fistula	Single tract; affected loops often angulated and tethered; describe origin and termination location
Complex fistula	Multiple tracts; asterisk appearance; +/-interloop abscess or inflammatory mass (phlegmon)
MESENTERIC FINDINGS	
Vasa recta distention	Also known as the comb sign in the literature; inflamed bowel loop with dilation of mesenteric vessels larger than adjacent to bowel loops
Fibrofatty proliferation	Increased fat adjacent to abnormal bowel, displacing bowel loops; usually along mesenteric border, unless perirectal; often associated with mesenteric border inflammation; if perirectal, then circumferential
Perienteric edema, inflammation	Increased attenuation (CT) or high T2 signal (MR) in mesenteric fat adjacent to abnormal bowel loops
Inflammatory mass	Ill-defined, masslike process of soft tissue attenuation and signal intensity (not water attenuation and signal intensity; also known as a phlegmon) usually associated with penetrating disease, such as complex fistula and inflammatory stranding in the mesenteric fat
Abscess	Mesenteric or peritoneal fluid collection with rim enhancement or internal gas
Amenable to percutaneous drainage	Well-formed collection >3 cm, accessible to intervention
Not amenable to percutaneous drainage	Not well formed, or <3 cm, or not accessible to intervention because of bowel, bony, or vascular structures
Adenopathy	>1.5 cm in short axis
Likely inflammatory	If <2 cm in short axis
EXTRAINTESTINAL FINDINGS	
Sacroiliitis	
PSC	Discontinuous, intrahepatic bile duct visualization and/or extrahepatic ductal wall thickening without significant upstream dilation
Venous thrombus, thrombosis (occlusive)	Mesenteric, portal, IVC, iliac, femoral, gonadal
Nephrolithiasis and cholelithiasis	
Avascular necrosis	Femoral head most common; if present, describe articular collapse

TABLE
41-2

Abdominal Radiology Society Nomenclature for Computed Tomography and Magnetic Resonance Enterography Dictation Impressions in Small Bowel Crohn's Disease

Findings	Description
Active inflammatory small bowel Crohn's disease (luminal narrowing present or absent)	Wall hyperenhancement in noncontracted small bowel segment; wall thickening, mesenteric changes are variable but often present
Quiescent or inactive small bowel Crohn's disease	Absent wall hyperenhancement, ± wall thickening, no mesenteric changes except fatty proliferation
Mixed fibrostenotic and active inflammatory small bowel Crohn's disease (a controversial classification to some; see text)	Stricture, wall thickening, wall hyperenhancement, luminal narrowing with upstream dilation; most strictures have inflammatory and fibrotic components
Penetrating Crohn's disease (added in addition to determination of active or mixed Crohn's disease)	Sinus tract and/or fistula; inflammatory mass; abscess; free perforation; associated with mixed fibrostenotic and active inflammatory small bowel Crohn's disease or active inflammatory small bowel Crohn's disease
Fibrostenotic small bowel Crohn's disease	Wall thickening, no wall hyperenhancement, absent mural edema (MRE only), no mesenteric changes, lumen narrowed, with upstream dilation

Baker ME, Fidler JL, Fletcher JG, Bruining DH, and other members of the SAR Crohn's Disease Focused Panel: Unpublished work in progress, 2014.

differentiation. Furthermore, accompanying mesenteric findings, such as vasa recta distention or fibrofatty proliferation, are almost always present. Hyperenhancement may be layered or stratified into two patterns, bilaminar and trilaminar. In the bilaminar pattern, only the inner wall hyperenhances (Figs. 41-12 and 41-13). This is often referred to in the literature as mucosal hyperenhancement. Because the mucosa may be destroyed, we prefer to describe rather than conclude that the mucosa is present. In the trilaminar pattern, there is inner and outer wall (sometimes referred to as serosal) hyperenhancement, with the intervening wall relatively hypoenhancing, giving a halo effect (Fig. 41-14). This pattern is much more commonly seen in MRE; it may very well be present in CTE but

is not as well identified because of poorer contrast resolution compared with MRE. There is likely no clinically significant difference between bilaminar and trilaminar hyperenhancement. Both are present with active inflammation. Hyperenhancement may be homogeneously transmural (Figs. 41-15 and 41-16), asymmetric, or patchy (Figs. 41-17 and 41-18). The hyperenhancement may at times be very subtle; viewing with narrow windows facilitates identification (see Fig. 41-18). When asymmetric, the pseudosacculation of the nonaffected segment is sometimes present (see Fig. 41-17).

Thickening. Bowel wall thickening, usually more than 1.5 to 2 cm, is another consistent feature of Crohn's disease. Although

Figure 41-12 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease of the distal ileum with penetrating disease: Bilaminar hyperenhancement. CT enterography in axial (A) and coronal (B) reconstructions show bilaminar hyperenhancement, severe wall thickening (>1 cm) (white arrow), and a fistulous tract extending cephalad (arrowhead) toward an abscess (black arrow).

Figure 41-13 Active inflammatory small bowel Crohn's disease of the distal ileum with mild luminal narrowing: Bilaminar hyperenhancement. MRE using HASTE (A, B) and postcontrast VIBE (C, D). A, B. HASTE images show increased signal because of edema and/or lymphatic distention (black arrow). C, D. Postcontrast VIBE images show a bilaminar hyperenhancement pattern, moderate wall thickening (5-10 mm), and vasa recta distention (arrowheads). There is also colitis (white arrow).

Figure 41-15 Active inflammatory small bowel Crohn's disease of the distal ileum with segments of normal lumen and mild luminal narrowing: Homogeneous enhancement pattern. Axial (A) and Coronal (B) CTE images show a long length of diseased ileum with homogeneous hyperenhancement and moderate wall thickening.

Figure 41-16 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease of the distal ileum: Homogeneous and trilaminar hyperenhancement, deep ulcers, and an intramural sinus tract. Postcontrast axial (A) and coronal (B) VIBE images from MRE show segments of trilaminar and homogeneous hyperenhancement. Axial (C) and coronal HASTE (D) images show deep ulcers (arrows) and an intramural sinus tract (arrowhead). There is moderate upstream dilation (4-5.9 cm). The vasa recta are also dilated.

wall thickening is most often symmetric (see Fig. 41-16), as with hyperenhancement, it may also be asymmetric (see Figs. 41-17 and 41-18). It is important that the bowel be distended when assessing bowel wall thickening. Thickening may be mild (3-4 mm), moderate (5-10 mm) or severe (>10 mm). When severe, especially when focal and short segment, causing obstruction, one may suspect that a complicating tumor is present (see later).

On MRE thickened, cobblestoning or pseudopolyposis may be present. These are patchy, sharply demarcated areas of high signal intensity along affected small bowel segments (Fig.

41-19). Additionally, pseudopolyposis may be identified as a papillary, endoluminal nodule that generally uniformly hyperenhances (Fig. 41-20).

On MRE there may be intramural edema in the thickened wall. This is identified on fat-saturated, T2-weighted images as a high signal (must be fat-saturated imaging because intramural fat may also cause an increased T2 signal; see Fig. 41-13).

Luminal Narrowing, Stricture Formation, and Upstream Dilation. Initially, when the disease is present, the bowel lumen is not significantly narrowed (see Fig. 41-18). However, as the

Figure 41-17 Active inflammatory small bowel Crohn's disease with and without luminal narrowing: Asymmetric changes. Axial (A) and Coronal (B) CTE images at one level show wall thickening along the mesenteric border, with a normal antimesenteric border (arrow). At this site of disease, the lumen is not narrowed. On the same images, there is another anterior, small bowel loop with trilaminar hyperenhancement, moderate wall thickening, and luminal narrowing. Just upstream, in the distal ileum, axial (C) and coronal (D) images show pseudosacculation (arrowhead).

Figure 41-18 Active inflammatory small bowel Crohn's disease without luminal narrowing: Subtle asymmetric changes. Axial (A) and Coronal (B) CTE images of the distal ileum show very subtle bilaminar hyperenhancement and mild wall thickening (arrow).

disease progresses, the affected bowel lumen narrows (see Figs. 41-14 and 41-15). As noted, luminal narrowing in Crohn's can be caused by spasm or the proliferation of smooth muscle and/or fibrous tissue. The two can be differentiated with MRE/CTE by the presence or absence of upstream dilation. Using dynamic, fluoroscopic MR techniques, one can also identify ballooning, upstream dilation caused by a fixed stricture. We define a stricture as an area of luminal narrowing associated with upstream dilation more than 3 cm (see later, "Mixed Fibrostenotic and Active Inflammatory Small Bowel Crohn's Disease"). When the upstream segment is less than 4 cm, it is considered mild, 4 to 5.9 cm is moderate, and more than 6 cm is severe.

Ulcer and Sinus Tract. Ulcerations can be identified on cross-sectional enterography, much more commonly with MRE. Images achieved with MR enteroclysis, with consistent and continuous luminal dilation, can provide sufficient resolution to detect early lesions of Crohn's disease, such as blunting, flattening, thickening, distortion of small bowel folds, nodularity, and aphthous-type ulcers. Differentiating an ulcer from a sinus tract and an ulcer from pseudopolypoidosis can be difficult. We have arbitrarily defined an ulcer as a wall defect that does not extend outside the bowel wall (Figs. 41-21 to 41-23). A sinus tract extends outside the lumen, but does not extend to adjacent organs. When a sinus tract is present, there is almost always

some degree of bowel angulation, loop separation, and/or tethering of the bowel or urinary bladder. Furthermore, there is almost always stricture formation. Pseudopolypoidosis has an intraluminal-endoluminal component. Aphthoid ulcerations may enlarge and coalesce to form deeper, usually linear, ulcerations, which frequently assume a longitudinal and transverse orientation. When longitudinal, these are called intramural sinus tracts. On T2-weighted images, they appear as thin lines of high signal intensity within the thickened bowel wall (see Figs. 41-16 and 41-23).

Simple and Complex Fistulae. A simple fistula is a single, soft tissue tract that extends from one loop of bowel to another or to another adjacent organ or structure, such as the urinary bladder or psoas muscle (Fig. 41-24). A complex fistula contains multiple tracts that extend to several loops of bowel and/or other organs or structures (Figs. 41-25 and 41-26). These can take on an asterisk appearance (see Fig. 41-26) and can be associated with an inflammatory mass or interloop abscess. As with sinus tracts, all small bowel fistulae from Crohn's disease are associated with stricture formation. On true FISP and HASTE sequences, sinus tracts and fistulae can present as higher signal linear- to tubular-shaped structures, often containing

Figure 41-19 Inflammatory pseudopolyps: MRI features. Axial true FISP scan of the distal ileum shows pseudopolyps as small nodular defects protruding through the thickened bowel wall (arrows).

Figure 41-20 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease: Inflammatory polyp at a stricture site. Axial (A) and Coronal (B) CTE images show a hyperenhancing polypoid filling defect representing an inflammatory polyp (arrow).

Figure 41-21 Active inflammatory small bowel Crohn's disease without luminal narrowing: Focal ulcer. A. Axial HASTE sequence shows subtle increased signal in the wall (arrow) from edema and lymphatic distention. There is a focal, very high-signal area representing an ulcer. B. On the coronal postcontrast-enhanced VIBE image, the ulcer enhances (arrow). There is also trilaminar hyperenhancement and distention of the vasa recta.

Figure 41-22 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease: Ulcer and sinus tract. **A.** Axial postcontrast VIBE image from MRE shows a bilaminar hyperenhancement and moderate wall thickening. Axial **(B)** and coronal **(C)** postcontrast VIBE images show an ulcer contained within the wall (arrow). Axial **(D)** and coronal **(E)** postcontrast VIBE images show a sinus tract extending outside the wall toward a tethered loop of small bowel (white arrowhead). **F.** Axial postcontrast-enhanced VIBE image shows an intermediate-sized, homogeneously enhancing lymph node (black arrowhead)

central high signal intensity because of their fluid content. However, these tracts may not contain fluid and may present on these T2-weighted pulse sequences as linear, low-signal tracts that hyperenhance on postcontrast-enhanced T1-weighted sequences.

Mesenteric Findings

Vasa Recta Distention. In most cases of active inflammatory Crohn's disease, the straight arteries or vasa recta arising from the mesenteric arcades and extending toward the small bowel are dilated. This has been described in the literature as the comb sign. Vasa recta distention is identified with CTE and MRE as short, parallel, low-attenuation or signal intensity linear structures perpendicular to the intestinal long axis of the diseased bowel. They are best demonstrated on contrast-enhanced CTE or T1-weighted

images as hyperenhancing linear structures (Fig. 41-27; also see Fig. 41-13).

Fibrofatty Proliferation. In many cases of Crohn's disease, there is increased fat adjacent to the affected bowel, displacing the small bowel loops, generally along the mesenteric border. This leads to loop separation. Fibrofatty proliferation of the mesentery develops in nearly 50% of patients with Crohn's disease and is the most common cause of bowel loop separation. The fibrofatty proliferation is the result of perivascular inflammation (Fig. 41-28).

Perienteric Edema and Inflammation. Perienteric edema or inflammation is identified as increased attenuation (CT) or high T2 signal (MR) in the mesenteric fat adjacent to affected segments of small bowel. The finding is much easier to identify

Figure 41-23 Deep ulceration. Axial (**A**) and coronal (**B**) true FISP MR images of the terminal ileum. Ulcers are visualized as thin lines of high signal intensity, longitudinally or transversely (fissure ulcers; arrows) oriented within the thickened bowel wall.

Figure 41-24 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease: Simple fistula, inflammatory mass and abscess.

A. Postcontrast-enhanced, axial CTE shows bilaminar hyperenhancement and moderate wall thickening of a loop of distal ileum. **B.** Just inferior to this, there is a small abscess laterally (white arrowhead), and the start of a single fistula is identified (arrow). **C.** The fistula is best identified in the coronal plane (arrow). **D.** More inferiorly in the pelvis, on the axial view, there is an inflammatory mass (black arrowhead).

Figure 41-25 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease with penetrating disease: Complex enterocecal, enteroenteric, enterosigmoid, enterovesicular fistula involving the right ureter, with abscesses. **A.** Postcontrast-enhanced, coronal CTE image shows bilaminar hyperenhancement and wall thickening of the terminal ileum and an enteroenteric, enterocecal fistula (arrowhead). **B.** Axial CTE image shows the enteroenteric and enterosigmoid fistula (arrowhead), an inflammatory mass surrounding the right ureter (filled with a stent), and two small abscesses (arrows). **C.** Coronal CTE image shows the fluid-filled enteroenteric and enterosigmoid fistula tract (arrowhead), as well as an abscess (arrow) between the fistula and urinary bladder dome. **D.** Axial CTE image shows the abscess (arrow) adjacent to the dome of the urinary bladder. At surgery, the bladder dome was involved.

on MRE as fat suppressed, T2-weighted pulse sequences (see Fig. 41-26).

Inflammatory Mass and Abscess

An inflammatory mass is defined as an ill-defined, masslike process of soft tissue attenuation or increased signal intensity (but not water attenuation–signal intensity) in the mesenteric fat, almost always associated with penetrating disease, which arises from mixed disease (fibrostenotic and acute inflammatory disease; see Fig. 41-24). An abscess is a well-formed, thick-walled, near-water to water attenuation collection in the mesenteric fat. An abscess should be described as amenable or not amenable to percutaneous drainage (see Figs. 41-12, 41-24, 41-25, and 41-27). This should be determined on the basis of size (>3 cm; generally, the size above which a pigtail catheter can be deployed) and whether the collection can be entered without traversing bowel, vessels, or bony structures. When using neutral oral contrast agents, it is very important to scrutinize the images carefully using scrolling techniques in the axial and coronal planes to differentiate an abscess from

a dilated loop of bowel, because both will contain near-water to water attenuation contents.

Adenopathy. Enlarged mesenteric lymph nodes are commonly present in patients with active inflammatory Crohn's disease. Enlargement is defined as more than 1.5 cm in the short axis. These are likely inflammatory if less than 2 cm. If more than 2 cm, especially if multiple, one should carefully scrutinize the adjacent, affected bowel for the presence of a tumor (see Fig. 41-22).

Extraintestinal Findings

Extraintestinal findings on MRE/CTE are relatively common. These include sacroiliitis (Fig. 41-29), primary sclerosing cholangitis (PSC), venous thrombosis, cholelithiasis, nephrolithiasis, and avascular necrosis, usually of the femoral head. PSC is identified as discontinuous, intrahepatic, biliary ductal visualization and/or extrahepatic ductal wall thickening without significant upstream biliary dilation. Common veins thrombosed in Crohn's include the superior mesenteric and portal veins,

Figure 41-26 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease with penetrating disease: Complex enteroenteric, enterosigmoid, enterovesicular fistula with perienteric edema and mural edema/distended lymphatics. Postcontrast-enhanced axial (A) and coronal (B) images with an asterisk-like appearance. Note that the wall of the dome of the urinary bladder is thickened. C. Sagittal HASTE image shows the high-signal, fluid-filled fistulous tract (black arrow) from the small bowel to the urinary bladder. Two axial, fat-saturated HASTE images show increased signal in the wall from intramural edema-lymphatic distention (D, white arrow) and perienteric edema-inflammation (E, white arrowhead).

Figure 41-27 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease with penetrating disease: Vasa recta distention, multifocal disease, sinus tracts, and abscesses. A. Coronal postcontrast-enhanced CTE image shows multifocal disease with bilaminar to homogeneous hyperenhancement and moderate wall thickening. Axial (B) and coronal (C) images through the terminal ileum show small interloop abscesses (arrowheads) and sinus tracts (arrows). The vasa recta are also distended.

Figure 41-28 Active inflammatory small bowel Crohn's disease with luminal narrowing: Fibrofatty proliferation. Axial (A) and Coronal (B) CTE images show bilaminar hyperenhancement, moderate wall thickening, and luminal narrowing of the neoterminal ileum. The affected loop is surrounded by excess fat (arrows).

Figure 41-29 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease: Sacroiliitis and severe small bowel dilation. Axial (A) and coronal (B) postcontrast-enhanced CTE images show bilaminar hyperenhancement, moderate wall thickening, and marked upstream bowel dilation (arrow). C. Axial images in the pelvis show right-sided sacroiliitis (arrowheads).

gonadal vein, iliac and femoral veins, and inferior vena cava (IVC).

Active Inflammatory Small Bowel Crohn's Disease

One of the major problems with the current literature concerning assessing active inflammation is that multiple reference standards are used as a surrogate for truth.⁸⁷ However, there is general consensus amongst investigators that active inflammatory disease is present when there is wall hyperenhancement in a thickened (>3 mm), noncontracted, small bowel segment. In

addition to this constellation of findings, there are almost always adjacent mesenteric changes, such as vasa recta distention. In acute inflammatory disease, the lumen can narrow but there should be no upstream bowel dilation. When assessed as such, the dictation should add the absence or presence of luminal narrowing (see Figs. 41-13 to 41-15, 41-17 to 41-19, 41-21, and 41-28).

In CTE and MRE, layered enhancement, or mural stratification, is thought to be highly specific for active inflammation.^{87,121} The degree of enhancement of these various layers

may reflect the underlying disease activity. However, it is not clear if bilaminar and trilaminar hyperenhancement indicate different processes. Most studies only describe layered enhancement or a striated pattern and do not distinguish between the two types of enhancement. Furthermore, it is likely that MRE more commonly identifies the trilaminar pattern than CTE simply because it is more sensitive to enhancement. The peripheral layer of hyperenhancement in the trilaminar pattern is generally much more subtle on CTE than the inner layer of hyperenhancement.

In studies that have relied on endoscopy as the reference standard, the level of enhancement follows the level of disease activity. However, when other standards are used, such as CDAI or blood markers, the correlation is less evident. It is important to note that the presence of acute inflammation does not exclude fibrosis.^{10,11,121} Further, enhancement can be secondary to factors other than acute inflammation, such as micro-vascular density and disease chronicity.¹²² Enhancing mesenteric lymph nodes and vasa recta distention are also highly suggestive of active inflammatory Crohn's disease.

The use of T2-weighted pulse sequences to predict disease activity has been less extensively investigated.^{88,121} On fat saturated sequences, increased T2 signal in the bowel wall indicates edema and is likely also predictive of the level of acute inflammation. Conversely, if there is no increased mural T2 signal, it is likely that a thickened loop of bowel is fibrotic (fibrostenosis alone without inflammation). However, as with T1 enhancement, fibrotic strictures can and often do occur concurrently with acute inflammation (fibrostenotic predominant with active inflammation).

Quiescent or Inactive Small Bowel Crohn's Disease

Quiescent disease is defined as absent or only minimal wall hyperenhancement with either a normal or thickened bowel wall (Fig. 41-30). Mesenteric changes should be absent, except for fibrofatty proliferation.

Inactive Crohn's disease can be associated with other phases of Crohn's disease in other portions of the gut. There may be a decrease in the lumen diameter and wall thickening but not active inflammation as identified in the "burned out" segment.

Mixed Fibrostenotic and Active Inflammatory Small Bowel Crohn's Disease

Mixed disease is defined as wall hyperenhancement, wall thickening and stricture formation (i.e., luminal narrowing with upstream dilation >3 cm in diameter) (Figs 41-31 to 41-33; also see Figs. 41-12, 41-16, 41-20, 41-22, 41-24 to 41-27, and 41-29). In this disease category, there are findings of both acute inflammation and of a fixed stricture causing some element of obstruction. Obstruction may be long standing and cause either marked bowel dilation or a stool sign (see Figs. 41-29, 41-31, and 41-32). The term *mixed* is controversial, especially with gastroenterologists. They are concerned that when fibrostenosis is added to the diagnosis, patients will not be treated medically. It remains to be seen if this group of patients are best treated with medical or surgical therapy. Another important aspect in patients with mixed disease is that penetrating disease may also be present (see Figs. 41-12, 41-24 to 41-27, and 41-33). In our experience, penetrating disease is never identified without mixed disease being present.

Figure 41-30 Quiescent disease. Axial (A) and coronal (B) CTE images are obtained before starting 6-mercaptopurine and show active, inflammatory, small bowel Crohn's disease of the terminal ileum with luminal narrowing, trilaminar hyperenhancement, and moderate wall thickening (arrows). Axial (C) and coronal (D) CTE images obtained 3 months later show a normal caliber lumen, minimal bilaminar to trilaminar hyperenhancement, and only mild wall thickening (arrows). The mucosa was normal at endoscopy.

Figure 41-31 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease: Moderate small bowel dilation with a stool sign. Postcontrast-enhanced axial (A) and coronal (B) CTE images show bilaminar to homogenous hyperenhancement, with marked bowel wall thickening in the distal ileum (arrows). C. Upstream to the stricture, there is a small bowel stool.

Figure 41-32 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease with an adenocarcinoma. Postcontrast-enhanced axial (A) and coronal (B) CTE images show bilaminar hyperenhancement and moderate wall thickening associated with marked upstream dilation (arrows). Distal to the disease, there is a soft tissue mass (arrowheads) representing an obstructing adenocarcinoma. The patient had long-standing Crohn's disease.

Penetrating Crohn's Disease

Penetrating disease is present when there is sinus tract or fistula formation, an inflammatory mass or abscess, or free perforation (see Figs. 41-12, 41-24 to 41-27, 41-30, and 41-33). This can be in addition to the determination of active inflammatory or mixed disease. However, in almost all cases, penetrating disease occurs when there is mixed disease present. This Crohn's subtype is characterized by transmural extension of the inflammatory process, with resultant fistula formation or perforation. Deep ulcers precede sinus and fistula formation to adjacent organs and the development of abscesses. On CTE, sinus tracts are small, linear- to tubular-shaped densities extending into the mesenteric fat, outside the wall of the bowel. On MRE, sinus tracts and fistulae are demonstrated by the high signal intensity of their fluid content on true FISP and HASTE images. When present, fistulae extend from the proximal aspect of strictured, active disease or just upstream to the

disease. Furthermore, the bowel affected by the fistulae are angulated and tethered and appeared fixed. There is loss of the normal undulating, curved contour of the small bowel. Interestingly, in cases of an enterovesicular fistula, urinary bladder gas is often absent. In these cases, there is a tethered loop of bowel, angulated toward the urinary bladder, with a linear strand of tissue extending toward the bladder and thickening of the wall of the bladder. There may be interloop inflammatory masses or abscesses. The multiplanar imaging capabilities of CTE and MRE are particularly useful in depicting complex fistulae and sinus tracts. Abscesses also occur in penetrating disease.

Fibrostenotic Small Bowel Crohn's Disease

Fibrostenotic disease is present when there is wall thickening, luminal narrowing, and significant upstream dilation (>3 cm), but no wall hyperenhancement. Furthermore, there is no mural edema (MRE) or mesenteric changes. In these cases, there is no

Figure 41-33 Mixed fibrostenotic and active inflammatory small bowel Crohn's disease with penetrating disease. **A.** Coronal HASTE image from MRE shows marked wall thickening of the terminal ileum with increased signal in the wall indicating mural edema–lymphatic dilation. There is also a sinus tract (white arrowhead) with increased signal in the tract. The upstream lumen is markedly dilated. **B.** Axial HASTE images show the terminal ileal wall thickening as well as an iliopsoas abscess (arrow) with heterogeneous signal. **C.** Postcontrast–enhanced axial VIBE image shows homogeneous hyperenhancement of the wall, moderate wall thickening, and the tract (black arrowhead) from the bowel to the abscess (arrow).

Figure 41-34 Fibrostenotic disease. **A.** Postcontrast-enhanced coronal CTE image shows mild wall thickening without hyperenhancement in the distal ileum (arrow). There is moderate upstream dilation. **B.** Small bowel series performed 3 months earlier shows the fixed stricture (arrow), with upstream dilation.

active inflammatory component. Small bowel obstruction is the predominant clinical manifestation of this disease subtype. CTE and MRE demonstrate a fixed narrowing of the involved bowel, with associated wall thickening. There is moderate to marked prestenotic dilation (Fig. 41-34).

ASSESSMENT OF DISEASE ACTIVITY

MRI and, to a lesser extent MDCT, have the potential to make the classification system of subtypes of Crohn's disease

more objective and reproducible and can help the clinician plan appropriate therapy. Differentiation between fibrotic and inflammatory stenosis is useful for selecting patients for medical (inflammatory) versus surgical (fibrotic) treatment. However, what has been published so far is based on different reference standards, including clinical indices, endoscopic scoring, biopsies, and surgical specimens.^{87,88} The problem of differentiating active inflammatory disease from fibrostenotic disease is further compounded by the fact that there is no accepted pathologic definition of these entities. Furthermore,

active inflammation and fibrostenosis coexist. Finally, patients who undergo surgical resection are distinctly different from those undergoing endoscopic biopsy because they have more severe disease.

Magnetic Resonance Imaging–Derived Disease Activity Indices

Although investigatory, several centers have compared MRE findings with endoscopic findings and have derived MRI scores (magnetic resonance index of activity [MaRIA] and activity index score [AIS]) to assess activity.^{123,124} The MaRIA is derived predominantly from findings in Crohn's colitis, whereas the AIS is derived from terminal ileal Crohn's disease based on initial histologic correlation and subsequently validated with endoscopy and endoscopic biopsies. The MaRIA is derived as follows:

$$\text{MaRIA} = (1.5 \times \text{wall thickness [in mm]}) + (0.02 \times \text{relative contrast enhancement of the bowel wall}) + (5 \times \text{the presence of edema}) + (10 \times \text{ulceration})$$

where relative contrast enhancement of the bowel wall is defined as the wall signal intensity postenhancement minus the wall signal intensity pre-enhancement divided by the wall signal intensity pre-enhancement; the presence of edema is based on hyperintensity on T2-weighted pulse sequences relative to the psoas muscle signal; and ulceration refers to deep depressions in the mucosal surface.

The AIS is derived as follows:

$$\text{AIS} = 1.79 + (1.34 \times \text{mural thickness [in mm]}) + 0.94 \times \text{mural T2 score}$$

where the mural T2 score is a qualitative score from 0 to 3, ranging from equivalent to adjacent, normal bowel wall signal to marked increased signal, nearly equivalent to the lumen.

Although these scores have been validated in small numbers of patients in two separate centers, more studies are necessary to determine their broad applicability.

Additional Imaging Considerations

POSITRON EMISSION TOMOGRAPHY, POSITRON EMISSION TOMOGRAPHY/COMPUTED TOMOGRAPHY, AND POSITRON EMISSION TOMOGRAPHY/MAGNETIC RESONANCE IMAGING

PET and PET/CT have been used recently to assess the level of inflammation in patients with Crohn's disease.¹²⁵⁻¹²⁸ The studies are preliminary but show that the addition of PET may assist in characterizing the disease further. The recent addition of PET

to MR (PET/MR hybrid imaging, or molecular MR) is an exciting new area of research.¹²⁹ As with other imaging investigations of small bowel Crohn's disease, accepted, validated surrogates of disease activity, supported by pathology, will be necessary to show efficacy.

CROHN'S JEJUNOILEITIS

Diffuse jejunoileitis forms a subset of Crohn's enteritis in which the distal ileum may be spared and disease progression may be craniad. It affects less than 10% of patients with Crohn's disease of the small bowel.⁷ Jejunoileitis affects younger patients, has a more acute onset, and requires more extensive bowel resections than distal Crohn's disease. In some cases, proximal progression with involvement of the duodenum has been noted.

CROHN'S ASSOCIATED ADENOCARCINOMA, NEUROENDOCRINE TUMOR, AND LYMPHOMA

An increased prevalence of small bowel carcinoma has been reported in patients with Crohn's disease involving the small bowel.^{130,131} Most investigators agree that Crohn's cancers exhibit special features—younger persons are more likely to be affected; the distal ileum is the usual site of involvement (most adenocarcinomas of the small bowel are proximal, centered around the ligament of Treitz); and areas of long-standing disease are more likely to undergo malignant change, rendering a radiologic diagnosis more difficult. Surgically bypassed bowel is another site more likely to be involved by tumor when radiologic diagnosis is extremely difficult, but this form of surgery is no longer performed. Carcinoma may also arise at the site of fistulae, so that any bleeding from these fistulae should be viewed with suspicion. A preoperative radiologic diagnosis is almost always impossible because of the absence of characteristic features; this is also usually the case at laparotomy. However, careful scrutiny of an obstructive site is essential to identify a mass (see Fig. 41-32). It is not surprising that patients with Crohn's carcinoma have a dismal prognosis, with an overall survival from the time of diagnosis measured in months.

Studies have shown an association between neuroendocrine tumors and Crohn's disease, with the tumor present in the face of disease.¹³² Although there has been some concern that lymphoma may develop in patients with Crohn's disease, evidence to date does not confirm the association of Crohn's disease and lymphoma.¹³³ However, with the increasing use of long-term immunomodulators and anti-tumor necrosis factor therapy, the risk of lymphoma may increase in Crohn's patients.

Inflammatory Disorders of the Small Bowel Other Than Crohn's Disease

STEPHEN E. RUBESIN

CHAPTER OUTLINE

Small Intestine as an Immunologic Organ

Parasitic Infestations

Ascariasis
Hookworm Infestation (Ancylostomiasis)
Strongyloidiasis
Anisakiasis
Tapeworm (Cestode) Infestation
Trematode (Flukes) Infestation
Giardiasis
Trypanosomiasis

Bacterial Infections

Tuberculosis
Yersiniosis
Salmonellosis
Campylobacteriosis

Fungal Infections

Histoplasmosis

Viral Infections

Drug-Induced Disorders

Ulcers and Stenoses Related to Nonsteroidal Anti-Inflammatory Drugs
Fluorinated Antipyrinidines

Inflammatory Disease in Immunodeficiency

Selective Immunoglobulin A and Common Variable Immunodeficiency
Graft-Versus-Host Disease
Typhlitis
Gastrointestinal Infections in AIDS
Human Immunodeficiency Virus Enteritis
Cytomegalovirus Infection
Cryptosporidiosis
Isosporiasis and Other Intracellular Protozoans
Mycobacterium Avium-Intracellulare Complex
Actinomycosis
Candidiasis

Differential Diagnosis

With increasing immigration, tourism, and globalization of the economy, infectious conditions of the small bowel are more likely to be encountered. Some of these patients with acute infectious diseases may undergo imaging studies for symptoms such as diarrhea or right lower quadrant pain (Figs. 42-1 and 42-2). This chapter presents a review of the wide spectrum of inflammatory and infectious disorders involving the small bowel other than Crohn's disease. Inflammatory disorders that

cause malabsorption are discussed in Chapter 43, and Crohn's disease is given special treatment in Chapter 41.

Small Intestine as an Immunologic Organ

The microflora of the upper gastrointestinal (GI) tract originates from swallowed food and from the oral cavity. Small amounts of bacteria and yeasts are present in the esophagus, stomach, and duodenum—about 10^6 bacteria/mL compared with 10^{11} to 10^{12} bacteria/mL in the distal small bowel and colon.¹

A variety of mechanisms prevent bacterial colonization of the small intestine. Secretion of water, electrolytes, and mucus by epithelial cells is an important component of host protection. Mucous secretions help prevent adherence of infectious agents to epithelial cells or penetration of toxins into these cells. Intestinal motility and fluid flow also impede bacterial colonization of the small bowel. Diarrhea caused by increased secretion of fluid and electrolytes also facilitates the passage of infectious agents out of the small intestine. Bacterial colonization may occur if there is small bowel stasis because of a motor disorder, diverticulosis, or strictures.

The small intestine is one of the largest immunologic organs in the body because it has an enormous surface area that is constantly exposed to foreign antigens. In healthy individuals, the small intestine is in a chronic state of low-grade inflammation and immune activity.² In most people, foreign antigens are eliminated without producing clinical symptoms. The small intestine can exclude foreign antigens without inducing autoimmune intestinal disease caused by cross-reactivity of foreign and host antigens.

The immune system includes intraepithelial lymphocytes, lymphoid tissue in Peyer's patches in the lamina propria, neutrophils, macrophages, and mast cells. Peyer's patches are unencapsulated lymphoid clusters spanning the lamina propria.² A specialized epithelium overlies the Peyer's patches; M cells in this specialized epithelium transport antigens to the underlying lymphoid tissue.

B cells in the lamina propria synthesize immunoglobulin A (IgA) and, to a lesser degree, IgM, IgG, and IgE. Intraluminal secretion of IgA inhibits bacterial adherence to the epithelium, preventing bacterial colonization. IgA also neutralizes bacterial toxins, minimizing any deleterious effects on epithelial cell function. IgA also blocks absorption of intraluminal antigens. IgA helps neutralize intracellular pathogens but does not cause their destruction.

Intraepithelial lymphocytes are primarily T cells. These cells lie in the basal epithelium, secrete cytokines, and are involved with antigen recognition and tolerance to oral antigens. They also perform immunosurveillance against abnormal epithelial

Figure 42-1 Acute infectious enteritis. An oncologist presented with 7 days of diarrhea and right lower quadrant pain after returning from a conference in the Caribbean. CT through the pelvis shows a thickened bowel wall (arrows) in the distal ileum with a mural stratification pattern of enhancing mucosa, thickened but low-attenuation submucosa, and enhancing muscularis propria. The patient's symptoms resolved within 3 weeks. A follow-up CT was normal. Although stool cultures were negative, the presumptive diagnosis was acute infectious enteritis.

cells. T cells are markedly increased in number in graft-versus-host disease, celiac disease, and protozoan infections.

Polymorphonuclear neutrophils differentiate in the bone marrow, leave the peripheral circulation, enter the lamina propria, and traverse the epithelium to enter the intestinal lumen. Neutrophils recognize and phagocytize antibody-coated bacteria. Macrophages in the lamina propria are derived from monocytes produced in the bone marrow. They also pass through the epithelium into the lumen and are important in bacterial phagocytosis and killing. Mast cells are found in all layers of the bowel wall. They contain granules with preformed mediators of inflammation such as histamine and 5-hydroxytryptamine and are important in the defense against intestinal parasites and food antigens.

Parasitic Infestations

Worms and protozoa infect more than 25% of the world's population. Helminths (worms) are divided into roundworms (nematodes), tapeworms (cestodes), and flukes (trematodes). Nematodes are round and unsegmented. They have a body cavity and are divided into separate sexes.² Cestodes are tapelike and segmented and are hermaphrodites. Trematodes are leaf-shaped and unsegmented and are also hermaphrodites.

ASCARIASIS

Ascaris lumbricoides is the most common intestinal worm, infecting about 25% of the world's population, most frequently people living in the tropics and subtropics.³ Ascariasis is acquired by ingesting mature eggs from contaminated soil, food, or water. Two to 3 weeks after ingestion of eggs, larvae develop in the small intestine. The larvae penetrate the mucosa, enter vessels in the bowel wall to reach the portal venous system, and migrate through the liver and heart to the lungs. The larvae then

Figure 42-2 Acute infectious ileitis. A young man presented with 2 weeks of right lower quadrant pain and mild diarrhea. This spot image from a peroral pneumocolon shows numerous smooth, ovoid, 3- to 5-mm nodules in the terminal ileum. Endoscopic follow-up was recommended because of the degree of nodularity and the confluent appearance of the nodules (arrow). Endoscopic biopsy specimens obtained several days later showed acute inflammatory changes in the terminal ileum. A follow-up barium study was normal. Although no stool cultures were obtained, the presumptive diagnosis was acute infectious ileitis.

penetrate the alveoli, enter the tracheobronchial tree, and are swallowed. Development is completed in the small intestine, where the worms attach to the mucosal surface of the midjejunum. Worms may grow up to 40 cm in length.

Symptoms include abdominal pain and malabsorption. If the worms are present in large numbers, ascariasis can cause small bowel obstruction resulting from luminal obstruction or intussusception.^{4,5} Mature worms that migrate into the bile or pancreatic ducts may cause cholangitis or pancreatitis.

Ascaris can be identified on plain abdominal radiographs, barium studies, and computed tomography (CT) scans. Long, smooth, convoluted tubular filling defects are seen in the intestinal lumen on barium studies (Fig. 42-3) or CT.⁶ If barium enters the worm's intestinal tract, a long, thin line of barium will be present within the tubular radiolucent filling defect caused by the worm (see Fig. 42-3). Small bowel folds are usually of normal size but may be enlarged. Small nodules reflect submucosal cysts surrounded by fibrotic tissue. The radiographic diagnosis can be confirmed by detection of ova in stool specimens.

HOOKWORM INFESTATION (ANCYLOSTOMIASIS)

Hookworms are small (8-10 mm) nematodes that infect almost 1 billion people worldwide.² The incidence of hookworm

Figure 42-3 Ascariasis. A young man presented with crampy abdominal pain and mild diarrhea 1 month after returning from a vacation in Central America. This spot image of the ileum from a small bowel follow-through shows numerous smooth, tubular filling defects in the barium column (representative ascarids identified by thick arrows). Barium faintly stains the body cavity of one worm (thin arrow). (From Forbes A, Misiewicz JJ, Compton CC, et al: *Atlas of Clinical Gastroenterology*, 3rd ed. Edinburgh, Elsevier-Mosby, 2005.)

disease has decreased markedly in the southern United States with improved sanitation. *Ancylostoma duodenale* is found in southern Europe, the Mediterranean region, and the western coast of South America. *Necator americanus* causes hookworm infestation in the southern United States, the Caribbean, and South America. Both species are found in India and southeast Asia.⁷ Near adult stage larvae and adult worms attach to the small intestinal mucosa. Ova are secreted into the feces. Infection results primarily from filarial invasion of the feet (in people who walk barefoot) or hands.

Although hookworm infestation can cause abdominal pain, diarrhea, or acute GI bleeding, iron-deficiency anemia is the most common clinical presentation. Peripheral eosinophilia is present in most patients.

The jejunal mucosa is edematous and hemorrhagic at sites of intestinal attachment. Hookworms have not been demonstrated on barium studies. Jejunal fold thickening and irritability may be present.⁸ Ileal strictures have also been reported.² Regional lymphadenopathy may be present. A definitive diagnosis requires the GI demonstration of ova in stool specimens or worms in jejunal aspirates or biopsy specimens.

STRONGYLOIDIASIS

Strongyloides stercoralis is a nematode usually found in the tropics and subtropics and in areas of poor sanitation or areas in which human waste is used as fertilizer. In the United States, strongyloidiasis is found in people living in Appalachia,⁹ military personnel returning from endemic regions, and patients who are immunocompromised because of malnutrition, steroid use, AIDS, or other causes.

Filariform larvae about 0.5 mm long penetrate the skin, migrate through the venous system to the lungs, penetrate the

Figure 42-4 Strongyloidiasis. This spot radiograph from a small bowel follow-through in a patient with a history of partial gastrectomy shows a tubular configuration of the pancreaticobiliary and alimentary limbs (long arrows). Moderate mucosal nodularity is present (open arrows). Saccululation and fold thickening are present in the pancreaticobiliary limb.

alveoli, enter the tracheobronchial tree, and are swallowed. The larvae are transformed into adult worms in the small intestine. The females penetrate the mucosa of the duodenum and proximal jejunum and live in the superficial layers of the proximal small bowel. Male worms are expelled. Female worms are about 2 mm in length.

Strongyloidiasis differs from other nematode diseases because autoinfection may occur; these infections may be life-threatening in an immunocompromised host. Eggs released into the intestinal lumen form rhabditiform larvae that develop into infective filariform larvae in the intestinal lumen or in the soil. The filariform larvae may reinvade intestinal mucosa or perianal skin. Most larvae die in lymphatics in the wall of the small bowel or in the mesentery.

Strongyloidiasis may cause a wide variety of clinical symptoms. These include abdominal pain, diarrhea, weight loss, and malabsorption.

Mild infestation by strongyloidiasis cannot be detected on imaging studies. With chronic infection, thickened folds are seen in the duodenum and jejunum on barium studies.¹⁰ With severe infection, the small bowel folds are effaced or obliterated, and the jejunum can assume a narrowed, tubular configuration (Fig. 42-4).¹¹⁻¹³ Strongyloidiasis is also a cause of papillary stenosis and small intestinal dilation. A definitive diagnosis can be made by duodenal aspiration or biopsy.

ANISAKIASIS

Members of the Anisakidae family are nematode parasites of marine mammals. *Anisakis* larvae are found in intermediate hosts such as squid and fish (e.g., salmon, cod, anchovy, tuna,

mackerel, Pacific pollock, Pacific red snapper, herring).¹⁴ Human infection is acquired by eating raw, inadequately cooked, or pickled fish. Anisakiasis is most common in areas in which raw fish such as sushi or sashimi is frequently eaten. Ingested larvae usually attach and invade the stomach, but small or large bowel involvement may occur. Edema and inflammation develop at the site of attempted larval penetration. Ulceration and perforation with the formation of inflammatory masses have been reported. Symptoms of small bowel involvement can mimic those of acute appendicitis, Crohn's disease, or small bowel obstruction.

Anisakis larvae have been detected on double-contrast studies of the stomach and colon as thin, curved, 5-mm filling defects in the shallow barium pool.¹⁵ Focal, irregular fold thickening may be seen in the small bowel. Strictures and short, ulcerated lesions have also been described.⁸ Perforation with mesenteric abscess formation may lead to a mesenteric mass or abscess detected on cross-sectional imaging studies.¹⁶

TAPEWORM (CESTODE) INFESTATION

Cestodes live as adults in the GI tract of definitive hosts and as cysticerci in the tissue of intermediate hosts. Humans are the definitive hosts for *Taenia saginata* (beef tapeworm), *Taenia solium* (pork tapeworm), *Hymenolepis nana* (dwarf tapeworm), and *Diphyllobothrium latum* (fish tapeworm). Humans are intermediate hosts for *Echinococcus granulosus*, *Echinococcus multilocularis*, and *Taenia solium*. These worms attach to the intestinal mucosa by a scolex. A connecting region is followed by the strobila and a ribbon-like chain of developing segments (the proglottids). The number of proglottids varies from 3 to 4000, and the length of the cestode varies from several millimeters to several meters.¹⁷

Humans are infected by eating inadequately cooked beef, pork, or fish (e.g., pike, salmon, trout, whitefish, turbot). After infected flesh is ingested, the cysticercus breaks down, releasing a scolex that attaches in the upper jejunum. The adult worm develops, and proglottids and ova are released into the lumen. Tapeworm infection usually causes no symptoms. Because of its long length (up to 4–6 m), *T. saginata* may cause obstructive symptoms. In contrast, *D. latum* may cause vitamin B₁₂ deficiency and macrocytic anemia.

TREMATODE (FLUKES) INFESTATION

A variety of flukes may involve the liver, biliary tract, and intestines. The genus *Schistosoma* infects more than 150 million people worldwide.² *S. mansoni* is endemic in Africa, the Middle East, and Latin America, *S. japonicum* is endemic primarily in Asia, and *S. haematobium* is endemic in the Middle East and Africa. *S. haematobium* mainly causes genitourinary disease but is occasionally found in the appendix. Because colonic infection by schistosomiasis is more common than small bowel infection, this disease is discussed in Chapter 58.

GIARDIASIS

Giardiasis is the most common parasitic disease worldwide. In the United States, giardiasis is usually found in the Rocky Mountain states.^{18,19} Surface water contaminated by feces

from wild animals is the principal source of infection. Cysts remain viable in cold water for 1 to 3 months² and can also survive the chlorine levels of many municipal water systems. Giardiasis is transmitted primarily by fecal-oral transmission from contaminated food and pets and occasionally by oral-anal contact. The risk of infection is greater in patients with immunodeficiency states and hypochlorhydria.

After cyst ingestion, trophozoites emerge in the duodenum and proximal jejunum. The trophozoites remain in the intestinal lumen or penetrate the mucus gel layer of the proximal intestine to attach to the glycocalyx of the enterocytes. The trophozoites do not invade the epithelium. Mature cysts are excreted in the stool.

The infection varies from the asymptomatic carrier state to self-limited diarrhea or chronic, watery diarrhea. Because the infection is patchy, biopsy specimens may be normal in infected patients. Some patients may have villous atrophy with crypt hyperplasia and variable inflammation, and others may have lymphoid hyperplasia.

The small intestine frequently appears normal on small bowel follow-through studies. In about 50% of patients, there is increased intraluminal fluid and rapid small bowel transit. Some reports have described thickened folds and irritability in the duodenum and jejunum (Fig. 42-5).^{20,21} Because barium studies are abnormal in fewer than 50% of infected patients and radiographic findings are nonspecific, the diagnosis depends on the detection of cysts and trophozoites on stool examinations, detection of trophozoites on duodenal biopsies or aspirates, or positive fluorescent antibody test.²²

Figure 42-5 Giardiasis. Spot image of the jejunum from an enteroclysis examination shows mildly thickened folds (arrows). Tiny mucosal nodules (open arrow) reflect enlargement of villi. (Courtesy Hans Herlinger, MD.)

TRYPANOSOMIASIS

Chagas' disease is caused by the protozoan *Trypanosoma cruzi*, spread by the bite of the reduviid bug. Chagas' disease is endemic in central Brazil, northern Argentina, and Venezuela but has also been reported in southern areas of the United States. It is estimated that 350,000 people in the United States are seropositive for this infection.²³ *T. cruzi* produces a neurotoxin that attacks autonomic ganglion cells throughout the body, including those in the heart, GI tract, urinary tract, and respiratory tract.²⁴ The esophagus, duodenum, and colon are the GI organs most commonly affected, resulting in secondary achalasia, megaduodenum, and megacolon. Involvement of the mesenteric small bowel leads to dilation of the small bowel, with delayed transit.

Bacterial Infections

Traveler's diarrhea and foodborne diseases are common problems related to tainted water supplies and improperly prepared or stored food. Bacteria are the organisms usually responsible for traveler's diarrhea, which explains why prophylactic use of antibiotics decreases the incidence of traveler's diarrhea.²⁵ Chemicals, viruses, and parasites are less frequent causes of traveler's diarrhea. Enterotoxigenic *Escherichia coli* is the most common cause of traveler's diarrhea. Enteroadherent and enteropathogenic *E. coli* are less frequent causes. *Shigella* and *Campylobacter jejuni* are the next most common pathogens, but these bacteria usually involve the colon. This infection is rarely diagnosed on imaging studies, because acute watery diarrhea develops during or shortly after a period of travel.

TUBERCULOSIS

Tuberculosis is endemic in Asia. Intestinal tuberculosis is uncommon in the West, usually occurring in the homeless, alcoholics, inmates, farm workers, immigrants, or people infected with human immunodeficiency virus (HIV). With the rise of AIDS and immigration, intestinal tuberculosis has become more common in developed countries. In one hospital in London with an extensive population of Asian immigrants, new diagnoses of tuberculosis were almost as common as new diagnoses of Crohn's disease.²⁶ The proposed mechanisms of infection of the GI tract include the ingestion of infected sputum or milk and hematogenous spread to submucosal lymphatics.²⁷ Intestinal tuberculosis frequently occurs without radiographic evidence of pulmonary disease.^{26,27}

Intestinal tuberculosis primarily occurs in the ileocecal region. The distribution of tuberculosis parallels the distribution of the lymphatics. In one autopsy series of over 1000 cases, 90% of patients had ileal disease and 75% had cecal disease. Other sites were not infrequently involved, however, including the ascending colon in 51%, transverse colon in 33%, descending colon in 23%, and appendix in 33%.²⁸ Skip lesions may be present.

The three classic forms of GI tuberculosis are the ulcerative, hypertrophic, and ulcerohypertrophic forms.²⁹ Sloughing of mucosa overlying submucosal tubercles results in ulceration. These ulcers usually appear as short (3–6 mm in length) collections perpendicular to the longitudinal axis of the bowel. The ulcers may be stellate or longitudinal. Extensive inflammation and fibrosis of the bowel wall result in the hypertrophic form

of tuberculosis associated with extensive mesenteric lymphadenopathy and adhesions. Bacilli are found primarily in necrotic mesenteric lymph nodes rather than the intestinal wall. Endoscopic biopsy specimens and tissue cultures are frequently negative.^{30,31} In one study, acid-fast bacilli and caseating necrosis were found in only 32% and 50% of patients with GI tuberculosis, respectively.³² In some cases, laparoscopic diagnosis with cultures and histologic examination of ascitic fluid may be helpful. Not infrequently, however, the diagnosis of tuberculosis is made only by pathologic examination of resected surgical specimens.

Complications of small bowel tuberculosis include strictures and obstruction, fistulas, enteroliths, and chronic appendicitis.

Barium studies may reveal perpendicular, stellate, or longitudinal ulcers of varying size with heaped-up margins in the colon or ileum (usually the terminal ileum).³³ Short or long strictures may be associated with nodular mucosa. A narrow, contracted cecum associated with a gaping ileocecal valve and disproportionate inflammation of the ascending colon are findings that help distinguish ileocecal tuberculosis from Crohn's disease (Fig. 42-6).³⁴ However, longitudinal ulceration, sinus

Figure 42-6 Ileocecal tuberculosis. This spot image of the ascending colon from a double-contrast barium enema shows disproportionately severe disease in the cecum versus the terminal ileum. The cecum is contracted and sacculated (*large arrow*). Granular and nodular mucosa (*open arrow*) is present in the cecum and ascending colon. The ileocecal valve is gaping (*curved arrow*). Only the distal 2 cm of the terminal ileum is narrowed (*thin arrow*). The remainder of the terminal ileum has a finely nodular mucosa (*arrowhead*). (From Rubesin SE, Bartram CI, Laufer I: *Inflammatory bowel disease*. In Levine MS, Rubesin SE, Laufer I [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000, pp 417–470.)

tracts, and fistulas in the terminal ileum may be indistinguishable from those in Crohn's disease on barium studies.

CT often reveals thickening of the ileocecal valve. The medial wall of the cecum is disproportionately thickened and is often associated with a soft tissue mass that engulfs the terminal ileum.³⁵ Wall thickening may be uniform or heterogeneous. Lymphadenopathy predominates in the pericecal region but may extend into the mesentery.

Historically, radiologic differentiation of tuberculosis from Crohn's disease was facilitated by predominance of the tuberculous inflammatory process in the cecum and ascending colon, with a patulous ileocecal valve lumen and thickened ileocecal valve lips in patients with tuberculosis.³⁶ Barium studies showing disease predominantly in the cecum and ascending colon with cecal contraction and CT showing low-attenuation lymph nodes indicative of caseous necrosis should suggest tuberculosis rather than Crohn's disease as the diagnosis in these patients.³⁷ However, tuberculosis and Crohn's disease may have a similar lymphatic distribution and overlapping radiographic findings.³⁶ The clinical history and patient demographics should therefore be considered before suggesting the diagnosis of Crohn's disease.

YERSINIOSIS

Yersinia are gram-negative cocci acquired after the ingestion of contaminated food or water. *Yersinia enterocolitica* is more frequently encountered than *Yersinia pseudotuberculosis* in the United States. *Yersinia* invades epithelial cells, enters Peyer's patches in the lamina propria and submucosa, and spreads to mesenteric lymph nodes.³⁸ Ileitis, colitis, mesenteric adenitis, periappendicitis, and hemolytic uremic syndrome have been reported.³⁹ Bacterial multiplication in Peyer's patches and regional lymph nodes can result in distant infections, including chronic hepatitis, ankylosing spondylitis, and lung and kidney infections.⁴⁰

Yersinia infection leads to the development of aphthoid ulcers overlying hyperplastic lymph follicles in the bowel. Hyperplasia of follicular and interfollicular regions results in massive lymphadenopathy.⁴¹ Acute vasculitis may cause ischemia.

The radiographic appearance in *Yersinia* enterocolitis depends on the course of infection. Early in the disease, aphthoid ulcers and thickened folds may be the predominant findings in the terminal ileum.⁴² Later in the disease, the ulcers disappear but thickened undulating folds persist (Fig. 42-7). The inflammatory process is distinguished from Crohn's disease by the absence of luminal narrowing, fissures, or fistulas. The inflammatory process usually resolves in 4 to 6 weeks.

SALMONELLOSIS

Salmonella infections in the GI tract may have distinct clinical forms, including gastroenteritis, typhoid fever, and an asymptomatic carrier state. Foodborne outbreaks resulting in diarrhea are usually caused by *Salmonella enteritidis* and *Salmonella typhimurium*, found in a wide variety of sources, including eggs, poultry, and livestock. Diarrheal outbreaks caused by fecal-oral spread from human reservoirs are less common.¹ *Salmonella* enter and multiply in M cells and enterocytes and then disseminate to lymphoid tissue and macrophages in the submucosa and mesenteric lymph nodes. The diarrheal form of salmonellosis varies from a few loose stools to a severe, watery,

Figure 42-7 *Yersinia* ileitis. This spot image of the terminal ileum from a double-contrast barium enema shows thickened, undulating folds (arrows) in the terminal ileum. No ileal narrowing is seen.

diarrheal state. The diarrhea usually lasts from 3 to 7 days. Bacteremia is uncommon, occurring in 6% to 8% of patients.¹

Typhoid fever is usually caused by *Salmonella typhi* and *Salmonella paratyphi*. Humans are the reservoir for *S. typhi*. The organism is transmitted by the fecal-oral route, so this disease is usually found in regions with contaminated water and poor waste treatment. In most patients, a brief episode of diarrhea precedes the febrile illness. A systemic, acute febrile illness then lasts for 3 to 5 weeks, accompanied by nonspecific symptoms such as headaches, malaise, abdominal discomfort, and arthralgia. Complications of *Salmonella* include GI bleeding and perforation related to a lymphoid reaction in the ileocecal region. Bacteremia can lead to other infections, including meningitis, pericarditis, orchitis, and splenic or liver abscesses. Hepatosplenomegaly may be present. Perforation or peritonitis may cause an adynamic ileus.

Salmonella may be manifested on barium studies by longitudinally oriented ulcers in the distal ileum overlying Peyer's patches.² Prominent lymphoid hyperplasia may be present, and vascular thrombosis may be seen. The disease is sometimes detected on CT performed to evaluate hepatosplenomegaly, right lower quadrant pain, and fever. CT may reveal circumferential thickening of the terminal ileum.⁴³ Barium studies may demonstrate nonspecific fold thickening in the terminal ileum.

CAMPYLOBACTERIOSIS

Campylobacter comprises a group of gram-negative rods, including *Campylobacter jejuni*, *Campylobacter fetus*, and *Campylobacter coli*. These organisms may cause an acute enteritis or

colitis, or affected individuals may remain in an asymptomatic carrier state.⁴⁴ Colonic infections may be severe, resulting in fulminant colitis with GI bleeding or toxic megacolon.⁴⁴ Systemic manifestations (e.g., arthritis, endocarditis, genital infections, urinary infections) may occur. Cross-reactivity of *C. jejuni* and neural antigens may result in Guillain-Barré syndrome.²

When the small intestine is involved, multiple superficial ulcers may develop in the distal ileum and region of the ileocecal valve. Barium studies may reveal thickened folds and aphthoid ulcers in the distal ileum and terminal ileum.^{45,46} The radiographic findings are indistinguishable from those of yersiniosis or early Crohn's disease.

Fungal Infections

HISTOPLASMOSIS

Histoplasma capsulatum is a dimorphic fungus commonly found in the Mississippi and Ohio River valleys. This fungus occurs in a mycelial form at ambient temperature and in a yeast form at body temperature.⁴⁷ The fungus usually infects older patients or immunocompromised hosts. Small bowel infection is common in patients with disseminated disease, but clinical symptoms are usually minimal. Ileocecal disease is characterized by ulceration, mucosal nodularity, strictures, and lymphadenopathy.⁴⁷ Intestinal perforation and peritonitis may also be seen.^{48,49}

Viral Infections

Numerous viruses may infect the small intestine, resulting in an acute diarrheal state. Radiologic studies are rarely performed in this clinical setting. The diagnosis can be made by viral cultures or by enzyme-linked immunosorbent assay (ELISA) or electron microscopy of stool specimens. Cytomegalovirus involving the small bowel is described later (see “Cytomegalovirus Infection”).

Drug-Induced Disorders

Drugs may cause a variety of abnormalities in the small intestine. Ischemia can result from systemic hypotension and hypovolemia, mesenteric arterial vasoconstriction, and slow mesenteric flow with venous thrombosis (Box 42-1).⁵⁰ Ischemia is discussed in Chapter 47. Anticoagulants may cause GI bleeding. Small bowel hypomotility can be caused by narcotics, drugs with anticholinergic properties, or neurotoxic side effects (Box 42-2). Drugs may cause malabsorption by a number of mechanisms, including interference with fat digestion and absorption; decreased gastric, pancreatic, and biliary secretions; increased intestinal transit; and small bowel mucosal injury (Box 42-3). Alcohol may also cause malabsorption by damage to intestinal crypts and villi. Metals such as aluminum, lead, gold, cadmium, mercury, zirconium, and iron may also damage small bowel epithelium.

ULCERS AND STENOSES RELATED TO NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

The small bowel is probably the most frequent site of gastrointestinal blood loss caused by nonsteroidal anti-inflammatory

BOX 42-1 DRUGS CAUSING SMALL BOWEL ISCHEMIA

Antihypertensive drugs and diuretics
Norepinephrine
Dopamine
Vasopressin
Digoxin
Cocaine
Ergotamines
Ergotamine
Methysergide
Oral contraceptives

BOX 42-2 DRUGS ASSOCIATED WITH SMALL BOWEL HYPOMOTILITY

Anticholinergic drugs
Phenothiazines

Verapamil
Clonidine
Vincristine
Narcotics

BOX 42-3 DRUGS ASSOCIATED WITH VARIOUS FORMS OF MALABSORPTION

Tetracycline
Cholestyramine
Colchicine
Neomycin
Methotrexate
Methylodopa
Allopurinol
Thiazide diuretics
Clofazimine

drug (NSAID) use. NSAID-related lesions have been detected with increased frequency by capsule endoscopy, enteroscopy, and enteroclysis. Small bowel ulcers are found at autopsy in approximately 8% of people who take NSAIDs.^{51,52} The mechanism of injury is unknown.

NSAID-related injury is found primarily in the ileum. Punctate, linear, or circumferential ulcers secondary to NSAIDs may cause GI bleeding or perforation. Chronic inflammation and scarring lead to the formation of characteristic weblike diaphragms and ringlike strictures in the small bowel.⁵³⁻⁵⁵ The mucosal diaphragms vary from slightly enlarged valvulae conniventes to thick, rigid, ringlike areas of narrowing. Pathologically, thick layers of hyalinized collagen are found to interdigitate with the muscularis mucosae.^{2,56}

NSAID-induced ulcers may be detected on air contrast enteroclysis. Any form of enteroclysis can detect small bowel strictures, but thin webs may be difficult to differentiate from prominent small bowel folds. Thicker webs may be seen as 2- to 5-mm thick rings encircling the bowel, associated with a tapered contour (see Chapter 46).⁵⁴

FLUORINATED ANTIPYRIMIDINES

Cells in the small bowel crypts have a high turnover rate and are particularly susceptible to chemotherapeutic drugs

Figure 42-8 5-FUDR chemotoxicity. CT through the upper pelvis shows homogeneous thickening of the wall of several small bowel loops (arrows).

that inhibit cell proliferation. Mucosal damage occurs within the first 3 days of chemotherapy. Mucosal regeneration occurs within several weeks after cessation of chemotherapy.⁵⁰ Enteritis may be caused by chemotherapeutic agents such as dactinomycin, bleomycin, cytarabine, doxorubicin, methotrexate, 5-fluorouracil, and vincristine.⁵⁰

Enteritis related to chemotherapy can sometimes be detected on CT performed in patients with known metastatic disease who have abdominal pain and diarrhea.

Two antipyrimidines, 5-fluorouracil (5-FU) and floxuridine (5-FUDR), are used for the treatment of colonic carcinoma metastatic to the liver. Direct infusion of these agents into the hepatic artery may cause severe gastroduodenal inflammation and ulceration.⁵⁷ Intravenous (IV) infusion may also produce a severe form of gastroduodenitis and associated enteropathy, manifested by nausea, vomiting, and diarrhea. CT (usually performed for follow-up of liver metastases) may reveal marked wall thickening in the distal ileum (Fig. 42-8).⁵⁸ Barium studies may show smooth, thickened, or effaced ileal folds (Fig. 42-9).⁵⁹ The diagnosis is suggested based on the clinical history of recent chemotherapy with 5-FU or 5-FUDR. The diagnosis is confirmed if there is improvement or resolution of clinical symptoms after cessation of chemotherapy and regression of radiologic abnormalities on follow-up imaging studies.

Inflammatory Disease in Immunodeficiency

SELECTIVE IMMUNOGLOBULIN A AND COMMON VARIABLE IMMUNODEFICIENCY

Selective IgA and common variable immunodeficiency are the most common primary immune deficiency states in adults.⁶⁰ In selective IgA deficiency, there are a decreased number of IgA-producing plasma cells in the lamina propria and submucosa.² GI tract infections are uncommon, however, because there is a compensatory increase in IgM-producing plasma cells. Bacterial and viral infections of the sinonasal regions cause most clinical complaints. There is a questionable increase in giardial

Figure 42-9 5-FUDR chemotoxicity. This spot image of the right lower quadrant shows three loops of neoterminal ileum with markedly thickened, relatively smooth folds (thin arrows) perpendicular to the longitudinal axis of the bowel. A portion of the infusion pump is identified (thick arrow). The ascending colon and cecum are surgically absent after a right hemicolectomy for colonic cancer.

infections. On barium studies, nodular lymphoid hyperplasia of the ileum is often present.

Common variable immunodeficiency is a heterogeneous group of varying B- and T-cell abnormalities that result in decreased production of IgG, IgM, and IgA, with an abnormal response to antigens and increased susceptibility to GI and respiratory infections. This heterogeneous disorder is associated with autoimmune diseases such as autoimmune hepatitis and sclerosing cholangitis. About one third of patients have the autoimmune form of atrophic gastritis with pernicious anemia and its increased risk of gastric carcinoma. Splenomegaly is frequently found. There may also be an increased risk of small bowel lymphoma in these patients.^{61,62}

Polyclonal B-cell lymphoid hyperplasia is present in the small intestine.² Lymphoid aggregates of T cells are present in the epithelium and lamina propria. A varying amount of villous atrophy is seen. Unlike gluten-sensitive enteropathy, however, a paucity of inflammatory cells is present in the lamina propria. A granulomatous reaction may also be present.

Barium studies may reveal extensive nodular lymphoid hyperplasia in the ileum (Fig. 42-10).^{63,64} The nodules are slightly larger and are more numerous and more widely distributed than the usual lymphoid follicles seen in the terminal ileum in children and young adults.

Giardiasis is common in patients with common variable immunodeficiency. Unlike disease in immunocompetent individuals, giardiasis in common variable immunodeficiency may cause severe mucosal damage and malabsorption. There is also an increased risk of colonic infections (e.g., salmonellosis) that can mimic ulcerative colitis.⁶⁰

GRAFT-VERSUS-HOST DISEASE

GI epithelium is damaged during the induction protocols for bone marrow transplantation. Anorexia, cramping, abdominal pain, and watery diarrhea occur immediately after induction by chemotherapy or radiation. Within 3 weeks, the enterocyte population is restored and symptoms subside. However, acute graft-versus-host disease (GVHD) develops in 30% to 50% of patients 3 to 11 weeks after allogeneic bone marrow transplantation. Acute GI symptoms include diarrhea, anorexia, vomiting, abdominal pain, and GI bleeding. A protein-losing enteropathy and secondary infections may occur.^{2,60} In patients with this disease, CD4⁺ T lymphocytes from the donor graft recognize host histocompatibility antigens as foreign, leading to a T cell–mediated attack on various tissues of the host. Tissue damage is most clinically evident in the skin, liver, mucous membranes, eyes, and GI tract. A maculopapular rash may be present on the palms, soles, and trunk. Acute watery diarrhea results from denudation of the intestinal epithelium. Biopsy findings vary from individual crypt cell death to total necrosis of the epithelium.⁶⁵ Submucosal edema is present. Acute GVHD is often complicated by cytomegalovirus, astrovirus, adenovirus, and *Clostridium difficile* infections.⁶⁶ Cholestasis and mild hepatocellular necrosis are reflected by abnormal liver function test results.

Chronic GVHD develops 3 to 13 months after transplantation and occurs without prior acute GVHD in 25% of patients. Esophageal changes are seen in 15% of patients, as described in Chapter 21.⁶⁷ Unlike acute GVHD, which is characterized by enterocyte necrosis, chronic GVHD is characterized by patchy fibrosis of the lamina propria and submucosa, with bacterial overgrowth.

Barium studies may confirm the diagnosis of acute or chronic GVHD and show the extent of disease. Thickened

folds and nodular mucosa may be seen (Fig. 42-11). A tubular (ribbon-like or so-called toothpaste) bowel may result from sloughing of the epithelium or such rapid transit that barium fails to coat the surface of the small bowel (Fig. 42-12).⁶⁸⁻⁷⁰ Barium may also adhere to the necrotic bowel surface, so that it is sometimes detected on abdominal radiographs or CT scans obtained after the initial barium study.^{71,72} CT may reveal a diffusely thickened small bowel wall (Fig. 42-13) with extensive submucosal edema (i.e., a target sign) or pneumatosis.⁷³ The mesentery may also be engorged, and ascites may be present.

Figure 42-11 Graft-versus-host disease. This spot image from a small bowel follow-through shows diffuse fold thickening in the jejunum.

Figure 42-10 Marked lymphoid hyperplasia in a patient with common variable immunodeficiency. This spot image from a small bowel follow-through shows innumerable 1- to 2-mm, round nodules in the distal ileum and terminal ileum. These lymphoid follicles are increased in number and extent in comparison to the usual lymphoid pattern confined primarily to the terminal ileum. The lymphoid follicles are not enlarged or confluent.

Figure 42-12 Graft-versus-host disease. This spot image from a small bowel follow-through shows that the jejunum and upper ileum have a diffusely narrowed, tubular appearance. In some loops the folds are markedly thickened (small arrow), whereas in other loops the folds are completely effaced (large arrows).

Figure 42-13 Graft-versus-host disease. CT through the top of the iliac crest shows extensive fold thickening (arrows) in mid small bowel loops.

Figure 42-14 Neutropenic enteritis. CT through the pelvis shows marked thickening of an ileal loop (arrows) with a mural stratification pattern because of low-attenuation submucosal edema and inflammation. Other images revealed marked cecal inflammation compatible with typhlitis.

TYPHLITIS

Neutropenic enterocolitis primarily affects the cecum and, to a lesser degree, the terminal ileum and appendix. Neutropenic enterocolitis is sometimes detected on CT scans to evaluate abdominal pain or fever in patients with various forms of leukemia (Fig. 42-14). This entity is discussed in detail in Chapter 58.

GASTROINTESTINAL INFECTIONS IN AIDS

About 50% of patients infected with HIV have chronic diarrhea.^{74,75} This can be related to AIDS enteropathy, infectious enteritis or colitis, motility disturbances, or drug-induced side effects of antiretroviral and antimicrobial agents.⁷⁶ A wide variety of viruses, bacteria, protozoa, and fungi can infect the small bowel in patients with AIDS. Some pathogens, such as *Mycobacterium avium-intracellulare*, are unique to AIDS. Other pathogens such as *Salmonella* have an increased incidence in patients with AIDS compared with immunocompetent patients. Patients with AIDS often have several concurrent infections, resulting in chronic diarrhea, malabsorption, protein-calorie malnutrition, and weight loss.

HUMAN IMMUNODEFICIENCY VIRUS ENTERITIS

The GI tract can be a portal of entry for HIV through tears in the rectal mucosa or even intact intestinal epithelium. HIV adheres to M cells in the intestinal epithelium.⁷⁷ The virus is subsequently delivered to intraepithelial lymphocytes, to lymphocytes in lymphoid follicles, and to macrophages in the lamina propria.⁷⁸ HIV infection results in near-complete destruction of CD4⁺ intraepithelial lymphocytes, leading to abnormal differentiation of IgA-secreting B cells and decreased numbers of mucosal IgA plasma cells. HIV also alters enterocyte differentiation.⁷⁹ As a result, HIV infection causes villous atrophy, crypt hyperplasia, edema, and chronic inflammation.⁸⁰ Nutrient absorption is impaired because of the loss of mature enterocytes.

An acute self-limited diarrhea lasting 1 to 3 weeks occurs in approximately one third of patients with acute HIV infection. The radiologist is not usually involved at this stage. AIDS enteropathy is defined as osmotic diarrhea and malabsorption occurring without evidence of other enteric infections. The radiologist may be asked to perform imaging studies on patients with chronic diarrhea, however, because endoscopy can establish the diagnosis in only about 40% of patients with suspected small bowel infection, and stool analysis can establish the diagnosis in only about 60% of patients.⁸¹⁻⁸³ Imaging studies are used to show the presence of small bowel disease and can sometimes aid in the differential diagnosis of these conditions.

CYTOMEGALOVIRUS INFECTION

Cytomegalovirus (CMV) is a double-stranded DNA virus in the herpesvirus group. A self-limited diarrheal infection can be seen in immunocompetent individuals.⁸⁴ After the initial infection, the virus enters a latent phase in circulating mononuclear cells throughout the GI tract.⁸⁵ The virus is usually reactivated when the host becomes immunocompromised. CMV accumulates in nuclear and cytoplasmic inclusions in epithelial cells, mononuclear cells, endothelial cells, fibroblasts, histiocytes, and smooth muscle cells of the GI tract. The infection results in varying degrees of inflammation and necrosis. Endothelial cell damage causes submucosal ischemia, with secondary epithelial ulceration. Ulceration leads to pseudomembrane formation and perforation.

In the small intestine, discrete erosions and penetrating ulcers are separated by normal mucosa.⁸⁶ Barium studies and CT usually show ulceration in the distal small bowel and terminal

ileum (Figs. 42-15 and 42-16) and in the cecum and ascending colon.^{86,87} However, some patients primarily have duodenal or jejunal disease or even diffuse small bowel disease.⁸⁸⁻⁹⁰ Intestinal perforation and ileocolic intussusceptions associated with lymphoid hyperplasia have also been described.⁹¹

CRYPTOSPORIDIOSIS

Cryptosporidium parvum is a unicellular, spore-forming coccidial protozoan that causes an acute self-limited diarrhea in immunocompetent patients. In patients with CD4⁺ counts less than 200 cells/mm³, however, *C. parvum* may cause a diffuse mucosal enteropathy, resulting in chronic, voluminous, watery diarrhea and malabsorption.⁹² This parasite is transmitted by the fecal-oral route via contaminated water or by person-to-person or pet-to-person contact.⁹³ Cryptosporidia are present in vacuoles beneath the membrane of epithelial cells at the villous tips but outside the epithelial cell cytoplasm. Infection results in a spectrum of findings, ranging from a normal histologic appearance to villous atrophy with severe inflammation.

Barium studies may reveal a variable degree of fold thickening in the duodenum and mesenteric small bowel (Fig. 42-17).^{94,95} One series reported proximal small bowel predominance with cryptosporidial enteritis.⁹⁶

ISOSPORIASIS AND OTHER INTRACELLULAR PROTOZOANS

Iso sporidia belli is an obligate intracellular protozoan acquired by ingestion of contaminated food or water or by homosexual

transmission.⁹⁷ Invasion of villous enterocytes results in villous atrophy and inflammation, often associated with extensive eosinophilic infiltration of the small bowel wall. Profuse watery diarrhea and malabsorption may ensue. Barium studies may reveal thickened small bowel folds, primarily in the duodenum and proximal small intestine.⁹⁸

Cyclospora cayetanensis is an obligate intracellular protozoan that also causes villous atrophy and acute and chronic

Figure 42-16 Cytomegalovirus infection in a patient with AIDS. CT through the pelvis shows marked wall thickening of the distal ileum (arrows). There also is irregularity of the mucosal surface caused by ulceration. (Courtesy Emil J. Balthazar, MD, and Hans Herlinger, MD.)

Figure 42-15 Cytomegalovirus infection in a patient with AIDS. This spot image of the terminal ileum from a small bowel follow-through shows large, lobulated folds (thin arrows) and barium-filled grooves caused by ulceration. Localized perforation is manifested by a barium-filled track (thick arrow) extending into the mesentery. (Courtesy Emil J. Balthazar, MD, and Hans Herlinger, MD.)

Figure 42-17 Cryptosporidiosis. This spot image of the mid small bowel shows mild, diffuse thickening of the folds. (Courtesy Hans Herlinger, MD.)

inflammation in normal or immunocompromised individuals. A chronic or relapsing watery diarrhea is usually present.

Microsporidia are a group of spore-forming, obligate, intracellular protozoans that infect the small intestine or disseminate to other organs, depending on the species.^{99,100} A chronic watery diarrhea is usually present.

Enterocytozoon bienersi infects 10% to 34% of patients with HIV infection and CD4⁺ counts of less than 50 cells/mm³. This protozoan infects enterocytes in the jejunum, resulting in villous atrophy and inflammation.¹⁰¹

MYCOBACTERIUM AVIUM-INTRACELLULARE COMPLEX

Two acid-fast obligate intracellular mycobacteria, *Mycobacterium avium* and *Mycobacterium intracellulare*, form the *Mycobacterium avium-intracellulare* (MAI) complex. These organisms are ubiquitous in the environment and are not enteric pathogens in immunocompetent patients. However, immunosuppressed patients exposed to aerosols, soil, or food containing MAI may develop disseminated infection. Genetic analysis of MAI isolated from AIDS patients has shown that most of these infections are caused by *M. avium*, so the term *M. avium* complex (MAC) is currently favored.¹⁰² HIV-infected patients with CD4⁺ counts less than 100 cell/mm³ may have disseminated MAC infection involving the liver, spleen, bone marrow, lymph nodes, and gastrointestinal tract. GI involvement may cause chronic diarrhea, abdominal pain, malabsorption, weight loss, hepatosplenomegaly, and lymphadenopathy.

The small intestine is the most severely infected portion of the GI tract. Jejunal and ileal predominance have been described.^{85,103,104} Barium studies may reveal thickened small bowel folds caused by infiltration of the lamina propria and submucosa by macrophages packed with acid-fast organisms (Fig. 42-18). Fine mucosal nodularity may also be seen as a result of villous blunting from diffuse infiltration of the lamina

propria. Aphthoid ulcers have also been described.¹⁰⁵ CT may reveal mesenteric lymphadenopathy, which is often more prominent than the retroperitoneal lymphadenopathy in these patients. Enlarged lymph nodes may have normal or low attenuation (Fig. 42-19). Hepatomegaly, splenomegaly, and ascites may also be detected in patients with disseminated infection.¹⁰⁶

Small bowel infection by *Mycobacterium tuberculosis* in patients with AIDS produces radiographic findings similar to those in immunocompetent patients with *M. tuberculosis*.¹⁰⁷ However, disseminated tuberculosis involving the peritoneum (Fig. 42-20), liver, spleen, and pancreas is more common in patients with AIDS.¹⁰⁸ The findings of tuberculous peritonitis include high-attenuation ascites, peritoneal

Figure 42-19 Mesenteric and retroperitoneal lymphadenopathy in a patient with *Mycobacterium avium* complex enteritis. CT through the tip of the liver shows a large left para-aortic nodal mass with a low-attenuation center (black arrow). Masslike infiltration of the small bowel mesentery (white arrow) is also present.

Figure 42-18 *Mycobacterium avium* complex enteritis. This spot image from a small bowel follow-through shows moderately thickened, smooth folds in the affected small bowel.

Figure 42-20 Tuberculous peritonitis in a patient with AIDS. This spot image from an enteroclysis examination shows extrinsic mass impressions (arrows) on the mesenteric border of midjejunal loops. Small bowel folds are also mildly enlarged.

and omental nodules, and low-attenuation lymphadenopathy (see Chapter 110).

ACTINOMYCOSIS

Actinomyces israelii is a filamentous bacterium that is part of the normal oral flora. GI actinomycosis usually involves the terminal ileum (Fig. 42-21) and appendix. A transmural infection mimicking Crohn's disease may be seen.¹⁰⁹ Fistulas are often present.

CANDIDIASIS

Fungal spores or hyphae of *Candida* may be found as a result of noninvasive colonization of blind loops or necrotic tissue. In contrast, invasive candidiasis may occur in the small intestine in patients with disseminated candidal infections, including patients with AIDS.^{110,111} Mucosal invasion causes ulceration and even perforation. Barium studies may reveal thickened small bowel folds.

Differential Diagnosis

The radiologist usually encounters infectious disease of the small intestine during the work-up of patients with acute right lower quadrant pain or during the work-up of patients with chronic diarrhea, malabsorption, and weight loss.¹¹² Acute

enteritis that causes abdominal pain rather than diarrhea can mimic appendicitis on clinical grounds. If CT performed to rule out acute appendicitis shows thickened ileal folds (Fig. 42-22) or regional mesenteric lymphadenopathy, various infectious pathogens (e.g., *Yersinia*) must be considered. However, a CT diagnosis of mesenteric adenitis is not indicative of a specific cause. A definitive diagnosis therefore requires stool cultures and biopsy specimens. Unfortunately, these cultures and biopsies are often negative or nonspecific in patients with acute infections. In such cases, follow-up CT or endoscopy may be needed to rule out small bowel lymphoma.

The inflammatory response to a variety of damaging agents such as chemical toxins, radiation, and infection is often similar. As a result, the CT or radiographic findings of thickened folds or villous enlargement are often nonspecific in patients with chronic diarrhea. When small bowel folds are thickened, the radiologist should therefore consider the age, travel history, and immune status of the patient. Proximal or diffuse small bowel fold thickening in patients with AIDS is caused by a variety of infections, including MAC, cryptosporidiosis (see Fig. 42-22), and isosporiasis. Patients receiving 5-FU or 5-FUDR may have intestinal chemotoxicity (see Figs. 42-8 and 42-9). Patients who have undergone allogeneic bone marrow transplantation may have GVHD (see Figs. 42-11 to 42-13) or CMV infection. Patients with proximal or diffuse small bowel fold thickening and a clinical history of malabsorption may have other types of disorders (see Chapter 43).

Disease involving the distal ileum usually indicates a disorder that has an affinity for lymphatic tissue in the small intestine, including Crohn's disease, *Yersinia* enterocolitis (see

Figure 42-21 Actinomycosis in a patient with AIDS. This spot image from a double-contrast barium enema shows mucosal nodularity (arrows) and irregular fold thickening in the terminal ileum.

Figure 42-22 Proximal small bowel fold thickening in a patient with AIDS. This spot image from a small bowel follow-through shows mildly thickened undulating folds (thin arrows) in a proximal loop of jejunum. Compare these jejunal folds with folds in the third portion of the duodenum (thick arrow). Normal duodenal folds should be slightly thicker than jejunal folds. Enteroscopic biopsy specimens revealed cryptosporidiosis.

Fig. 42-7), tuberculosis (see Fig. 42-6), and lymphoma. In patients with acute diarrhea, aphthoid ulcers are not specific for Crohn's disease because they reflect nonspecific inflammation of lymphoid tissue with erosion of the overlying mucosa. Any acute infection or inflammatory process can therefore lead to the development of aphthoid ulcers or thickened folds in the terminal ileum. In patients with thickened folds in the terminal ileum, an acute infection such as yersiniosis should be favored. Unfortunately, it may be difficult to obtain a definitive diagnosis in these patients because cultures and biopsy specimens are often negative for a specific pathogen.

Aphthoid ulcers, mesenteric border ulcers, cobblestoning, strictures, and fistulas should be highly suggestive of Crohn's disease in patients with chronic diarrhea (see Chapter 41). However, these findings are not always specific for Crohn's disease. If, for example, there is a clinical history of an immunodeficiency state or if the patient has lived in a region of the world in which tuberculosis is endemic, then tuberculosis (see Fig. 42-6), actinomycosis (see Fig. 42-21), Behçet's disease, and cytomegalovirus (see Figs. 42-15 and 42-16) should be considered, depending on the clinical history. The CT findings of bowel wall thickening, mesenteric lymphadenopathy, and mesenteric infiltration or abscess formation also are not specific for Crohn's disease, so further work-up is required.

Florid lymphoid reactions in the terminal ileum may result from prior enteric infection, immunodeficiency states

(in particular, common variable immunodeficiency), and lymphoma. Small (1-2 mm), round, uniform nodules separated by normal mucosa are indicative of lymphoid hyperplasia (see Fig. 42-23), which can probably be followed without further diagnostic testing. However, lymphoid nodules that are larger (>2 mm), more confluent, and not round, smooth, and uniform should be investigated for lymphoma (Fig. 42-24).

Small bowel wall thickening on CT is not a specific finding. However, a mural stratification pattern with a low-attenuation submucosa suggests a vascular or inflammatory process (see Fig. 42-1), but not a malignant tumor. Lack of contrast enhancement should suggest necrosis and a possible vascular component to the disease. Fat deposition in the small bowel submucosa should suggest Crohn's disease. Ileal wall thickening in patients with AIDS may be caused by inflammatory conditions or AIDS-related lymphoma (Fig. 42-25).

Lymphadenopathy adjacent to abnormal small bowel loops is not a particularly helpful finding because it can be seen with infectious disorders, Crohn's disease, carcinoid tumor, intraperitoneal metastases, and lymphoma. Extensive mesenteric lymphadenopathy in patients with chronic diarrhea or malabsorption is typically seen in patients with gluten-sensitive enteropathy, Whipple's disease (Fig. 42-26), and MAI infections. Lymphadenopathy in celiac disease is usually reactive, but lymphoma cannot be excluded.

Figure 42-23 Lymphoid hyperplasia in the terminal ileum. This spot image from a double-contrast barium enema shows discrete, round, uniformly sized, one to two radiolucent filling defects in the terminal ileum separated by normal mucosa.

Figure 42-24 Mantle cell lymphoma in the terminal ileum. This spot image from a small bowel follow-through shows small, round, ovoid or polygonal nodules ranging from 1 to 4 mm. The nodules are confluent in some areas (arrows). This type of mucosal nodularity requires endoscopic biopsies to rule out lymphoma. The nodularity does not resemble cobblestoning because transversely and longitudinally oriented barium-filled clefts are not seen.

Figure 42-25 Ileal wall thickening in a patient with AIDS. CT through the pelvis shows marked (1.5–2 cm) wall thickening (arrows) of uniform attenuation in the terminal ileum. The medial wall of the cecum is also thickened. Biopsy specimens revealed lymphoma. Marked wall thickening of uniform attenuation should be considered highly worrisome for small bowel lymphoma.

Figure 42-26 Lymphadenopathy in Whipple's disease. **A.** CT through the liver shows low-attenuation lymphadenopathy in the retrocaval, retrocrural and left para-aortic (arrow) regions. **B.** An image caudal to **A** shows marked mesenteric lymphadenopathy (arrows) of more uniform and higher attenuation.

Differential Diagnosis of Fold Enlargement in Malabsorption

Malabsorption is caused by a variety of diseases originating in the liver and biliary tree, pancreas, and small intestine.¹⁻³ Normal digestion and absorption are presented as a background for understanding intestinal malfunction. A description of diseases of the small intestine that result in malabsorption is then presented.

Digestion and Absorption

The components of most foods (carbohydrates, proteins, and fats) cannot be used in their natural state. Foods must first be digested and then absorbed by the gastrointestinal (GI) tract. Proper functioning of the stomach, liver and biliary tree, pancreas, and small bowel and, to a lesser degree, salivary glands

and colon, is required for normal digestion and absorption of food.

CARBOHYDRATE DIGESTION AND ABSORPTION

Carbohydrates account for 40% to 50% of daily caloric intake.⁴ Ingested carbohydrates are derived from plants, except for lactose, which originates in dairy products. Simple sugars include the monosaccharides, fructose and glucose, and the disaccharides, sucrose and lactose. Starches are soluble polymers of glucose found in the cell walls of plants. The starches are α -amylose, a linear polymer of glucose, and amylopectin, a branched form of glucose. Dietary fibers are nondigestible carbohydrates (nonstarch polysaccharides) that are structural components of plant cell walls.

The GI tract is adapted for digesting carbohydrates to a monosaccharide form that can be transported across the epithelium of the small intestine. Luminal digestion of starches is accomplished by amylase secreted by the parotid gland and pancreas. Salivary amylase is of minor importance because this enzyme is deactivated in the acidic environment of the stomach. Amylase digestion of starches is so efficient that starch digestion is more dependent on the form of the starch than on the availability of luminal amylase.⁴ Amylase deficiency is present only in cases of severe pancreatic insufficiency.

Enzymes on the apical membrane of the enterocytes are responsible for further digestion of the products of luminal digestion and breakdown of disaccharides. For example, sucrose isomaltase is an enzyme that cleaves sucrose into glucose and fructose. Brush border lactase cleaves lactose into glucose and galactose. This enzyme is critical for mammalian survival because early nutrition is provided by the mother's milk.⁴ The monosaccharides are then brought across the epithelium by passive diffusion, facilitative transport of proteins, or sodium-coupled active transport.

Colonic bacteria digest dietary fiber that reaches the colon, producing a variety of products, including short-chain fatty acids, methane, and hydrogen. Short-chain fatty acids are rapidly absorbed in the colon, providing energy for colonic epithelial cells.

Digestion of lactose, sucrose, and starches is incomplete because digestion depends on the type of food and contact time with the brush border. Between 2% and 20% of starch is not digested.⁴ Most small bowel diseases result in global dysfunction of the intestinal mucosa, leading to carbohydrate malabsorption, with subsequent diarrhea, flatulence, and weight loss. Specific disaccharidase deficiencies result in similar symptoms. For example, trehalose is a disaccharide of glucose found in insects, yeasts, and mushrooms. As a result, people who are trehalase-deficient have severe diarrhea after ingestion of mushrooms.

PROTEIN DIGESTION AND ABSORPTION

Proteins in the lumen of the GI tract derive from the diet (70-100 g/day), from salivary, gastric, pancreatic, and biliary secretions (30 g/day), and from sloughed epithelial cells (30 g/day).⁵ Protein digestion begins in the stomach. Inactive precursors (pepsinogens) are secreted from chief cells and are activated to pepsins in the acidic environment of the stomach. Proteins in the gastric lumen are digested to a mixture of large polypeptides, smaller oligopeptides, and free amino acids.

The exocrine pancreas secretes five inactive precursor zymogens into the duodenal lumen. Enteropeptidase (enterokinase) on the brush border of the duodenal enterocytes converts trypsinogen into trypsin. Trypsin then activates the remainder of the pancreatic zymogens—chymotrypsinogen, proelastase, and procarboxypeptidases A and B.⁵ These pancreatic enzymes break proteins into oligopeptides (60%-70%) and free amino acids (30%-40%).⁵ Peptidases on the brush border of the enterocytes further degrade the intraluminal oligopeptides, resulting in a mixture of tripeptides, dipeptides, and free amino acids. Distinct transport systems separately transport free amino acids and peptides of two to three amino acids into the epithelial cells. Various peptidases within the enterocytes further digest the small polypeptides. Amino acids leave the enterocytes via transport mechanisms across the basal membrane, passing into the portal circulation.

FAT DIGESTION AND ABSORPTION

The sources of fat include diet (120-150 g), biliary secretions (40-50 g), and sloughed intestinal cells and bacteria.⁶ Most dietary fat is composed of neutral fats, long-chain triglycerides. Phospholipids and sterols (including cholesterol) comprise only a small percentage of dietary fat.⁶

Lipid digestion begins in the stomach with the hydrolysis of triglycerides by gastric and salivary lipase; 20% to 30% of intraluminal fat digestion occurs in the stomach. The grinding action of the antrum helps reduce triglycerides into smaller particles. The fat globules are dispersed in a stable form with a large surface area, termed *emulsification*. Gastric lipid digestion has an increased role in patients with cystic fibrosis or a partial gastrectomy.⁶

After chyme reaches the small intestine, bile salts and lecithin secreted by the liver solubilize the fat, allowing the fat to be broken into smaller droplets by the agitating action of the small bowel. Lipolytic enzymes secreted by the pancreas break triglycerides, phospholipids, and sterol esters into their component monoglycerides and free fatty acids. Bile salts combine with the monoglycerides and free fatty acids to form micelles. The micelles deliver the breakdown products of fat to the microvilli of the epithelial cell brush border.

After brush border uptake, long-chain fatty acids and monoglycerides are delivered to smooth endoplasmic reticulum in the cytoplasm for resynthesis into complex lipids.⁶ Phospholipids, an important component of cell membranes, are synthesized in the rough endoplasmic reticulum. Triglycerides resynthesized in the endoplasmic reticulum of enterocytes are secreted by enterocytes as lipoproteins. These lipoproteins are multimolecular aggregates of lipid and protein, with a configuration that allows transport through aqueous intracellular fluid or plasma. Lecithin is the primary phospholipid in lipoproteins

and is derived primarily from bile salts (10-20 g/day) or diet (5-10 g/day). Cholesterol is primarily derived from biliary secretions (1-2 g/day), with a minor component (0.2-0.5 g/day) from the diet.

Most dietary fat enters the lymphatic circulation through lacteals located in each villus and is then passed via mesenteric lymphatics to the thoracic duct and superior vena cava. About 25% of triglycerides are transported to the liver bound to albumin.

Digestion of fat is very efficient. Almost all dietary triglyceride is absorbed by enterocytes. No ingested triglyceride is found in the colon. The small amount of fecal fat (<7 g/day) is derived from phospholipids in sloughed intestinal membranes or intestinal bacteria. After micelle delivery, bile salts return to the small bowel lumen to solubilize more free fatty acids and monoglycerides. Eventually, conjugated bile salts (95%) are resorbed in the ileum via an active sodium-coupled process. Some bile salts are passively absorbed in the proximal small intestine. Fecal loss of bile salts is balanced by synthesis of bile in the liver.

FLUIDS AND ELECTROLYTES

Diarrhea and malabsorption are not synonymous. Malabsorption may occur in some diarrheal states. A large volume of fluid (8-10 L) enters the GI lumen each day, but only 100 mL of fluid is normally excreted in the feces.⁷ The daily fluid load includes about 2 L of oral intake, 0.5 to 1.5 L of saliva, 2.5 L of gastric juice, 0.5 L of bile, 1.5 L of pancreatic secretions, and 1 L of intestinal secretions. The small bowel absorbs about 7 L of fluid daily, with 1.5 to 1.9 L of fluid reaching the colon. The colon is capable of resorbing up to 4 L of fluid on a daily basis. Diarrhea therefore occurs if more than 4 L of fluid reaches the colon or if abnormally functioning colonic mucosa cannot resorb the 1.9 L of fluid that normally enters the colon each day.

Anatomic Classification of Malabsorption

In summary, carbohydrate digestion requires a functioning pancreas and small bowel brush border enzymes. Normal protein digestion requires adequate gastric and pancreatic function and small bowel brush border enzymes. Fat digestion requires normal hepatic, biliary, exocrine, pancreatic, and small bowel function. An anatomic classification of malabsorption by abnormalities of the liver, biliary tree, stomach, and small intestine aids the radiologist in understanding malabsorption (Table 43-1).³

HEPATOBIILIARY AND PANCREATIC DISORDERS

Bile salt insufficiency caused by biliary obstruction or decreased hepatic synthesis leads to mild malabsorption. Any disease that destroys pancreatic exocrine tissue decreases bicarbonate and pancreatic enzyme secretion. Maldigestion does not occur until 90% of the pancreatic exocrine tissue has been destroyed.⁴ The most common cause of pancreas-related maldigestion is alcohol-related pancreatitis. Patients with cystic fibrosis have malabsorption, but this is a less common disease.

TABLE 43-1 Anatomically Oriented Classification of Malabsorption

Organ	Disease or Condition	Pathophysiology
Stomach	Zollinger-Ellison syndrome Postgastrectomy	Pancreatic enzyme inactivation by acid Rapid transit of nutrients, dilution of pancreatic enzymes
	Pernicious anemia	Intrinsic factor deficiency (vitamin B ₁₂ malabsorption)
Pancreas	Chronic pancreatitis, cystic fibrosis, pancreatic cancer	Decreased pancreatic enzyme and bicarbonate secretion
Liver, biliary tree	Severe parenchymal liver disease	Decreased bile salt formation
	Cholestatic liver disease (primary biliary cirrhosis, drug-induced cholestasis), bile duct obstruction (bile duct carcinoma, pancreatic cancer, gallstones, sclerosing cholangitis)	Decreased bile salt delivery to duodenum
Small intestine	Jejunal diverticulosis, scleroderma, small intestinal fistulas, stricture in Crohn's disease, diabetes, pseudo-obstruction	Stasis with bacterial overgrowth, bile salt deconjugation
	Crohn's disease, small intestinal resection, cholecystocolonic fistula	Increased bile salt loss
	Lactase deficiency, Crohn's disease	Disaccharidase deficiency
	Celiac disease, tropical sprue, Whipple's disease, eosinophilic gastroenteritis, radiation enteropathy, Crohn's disease, intestinal ischemia, ileal resection	Loss of normal epithelial cells
	Abetalipoproteinemia	Nonformation of chylomicrons
	Lymphangiectasia, lymphoma, tuberculosis, carcinoid	Lymphatic obstruction
	Diabetes mellitus, giardiasis, adrenal insufficiency, hyperthyroidism, hypogammaglobulinemia, amyloidosis, AIDS	Multiple causes

From Rubesin SE, Rubin RA, Herlinger H: Small bowel malabsorption: Clinical and radiological perspectives. *Radiology* 184:297–305, 1992.

GASTRIC DISORDERS

Diseases of the stomach may cause mild malabsorptive states. Patients with pernicious anemia have decreased production of intrinsic factor, leading to vitamin B₁₂ deficiency. In patients with Zollinger-Ellison syndrome, inflammation and ulceration in the duodenum and first several loops of jejunum cause diarrhea, not malabsorption. About one third of patients with Zollinger-Ellison syndrome have diarrhea related to gastric hypersecretion and intestinal mucosal damage. Mild malabsorption results from excess acid entering the duodenum, which inactivates pancreatic enzymes.

SMALL BOWEL DISORDERS

Malabsorption can result from a wide variety of mechanisms beginning in the intestinal lumen and extending deep to the small mesentery (see Table 43-1).

Bacterial Overgrowth (Intraluminal Stasis)

Any disease that causes stasis in the lumen of the small intestine can lead to bacterial overgrowth and small bowel dysfunction (Box 43-1).³ Disorders that cause chronic small bowel obstruction (e.g., Crohn's disease, adhesions) may result in stagnation and bacterial overgrowth. Diseases with intrinsic small bowel hypomotility (e.g., diabetes, scleroderma, jejunal diverticulosis) can also lead to stasis and bacterial overgrowth. Stasis in surgical blind loops or the afferent loop of a gastrojejunostomy can also result in bacterial overgrowth.

In patients with bacterial overgrowth, malabsorption is related to several mechanisms, including intraluminal bacterial deconjugation of bile salts and fermentation of carbohydrates. Concomitant epithelial cell dysfunction may be present. Bacterial digestion of malabsorbed fat forms compounds that

can stimulate small bowel or colonic secretion. Solutes of malabsorbed carbohydrates and deconjugated bile salts are also osmotically active, resulting in water and electrolyte loss.

Brush Border Disease

Brush border enzyme deficiencies or transport mechanism deficiencies may cause osmotic diarrhea, malabsorption, or both. The most common example of osmotic diarrhea caused by brush border disaccharidase deficiency is so-called lactase deficiency (lactose-phlorizin hydrolase deficiency) with lactose intolerance.⁴ The norm for most people is for brush border lactose-phlorizin hydrolase levels to decline in older children and adolescents to 5% to 10% of early childhood levels. As a result, lactase-phlorizin hydrolase deficiency is the norm, and the ingestion of dairy products can lead to diarrhea, flatulence, and cramps in most adults. Preservation of lactose-phlorizin hydrolase is an autosomally recessive trait, found typically in northern Europeans. Intermediate activity of this enzyme is found in heterozygotes.

Mucosal Damage

Inflammation or necrosis of crypt cells and immature villous cells causes secretory diarrhea. Blood, pus, and mucus in the intestinal lumen lead to osmotic diarrhea. Widespread epithelial damage is therefore characterized by a combination of osmotic and secretory diarrhea and nutrient malabsorption. Diseases that destroy proximal small bowel epithelium cause generalized malabsorption of fats, proteins, carbohydrates, iron, and folate, whereas diseases that damage distal ileal mucosa primarily cause malabsorption of fat because of bile salt loss and vitamin B₁₂ deficiency. Mucosal diseases causing malabsorption typically involve relatively long segments of small bowel. These diseases are relatively uncommon, however; they

*Disorders typically having a malabsorptive state are highlighted in bold.

include celiac disease, tropical sprue, Whipple's disease, and eosinophilic enteritis.

Postmucosal Disease

Any disorder that obstructs lacteals in the villi or lymphatics in the small bowel mesentery may cause fat malabsorption. In primary lymphangiectasia, for example, abnormal formation of lymphatics results in impaired absorption of chylomicrons and fat-soluble vitamins and loss of lymph into the intestinal lumen from lymphoenteric fistulas.

Diseases with Multifactorial Causes

Malabsorption is caused by several mechanisms in many diseases. In amyloidosis, for example, malabsorption can be attributed to stasis with bacterial overgrowth, mucosal destruction caused by ischemia, and disruption of nutrient absorption by amyloid deposition in the lamina propria. Fat malabsorption in hyperthyroidism is attributed to rapid small bowel transit.

Diagnosis of Malabsorption: Clinical Perspective

Malabsorption is characterized by diarrhea, steatorrhea, excessive gas, abdominal pain, and weight loss. Diarrhea is caused by decreased intestinal absorption, colonic secretion of fluid induced by hydroxy fatty acids, and osmotic overload of bile salts and fatty acids. *Steatorrhea* is the term used for the bulky, foul-smelling, greasy stools caused by the malabsorption of fat. Excessive gas production is related to fermentation of carbohydrates by intestinal bacteria and results in borborygmi, flatulence, and abdominal distention. Abdominal pain has a variety of causes, including pancreatic inflammation, biliary disease, small bowel obstruction, and ischemia.

Unfortunately, adults with malabsorption often have an insidious presentation. Steatorrhea may be so mild that it is unrecognized by the patient. Mild steatorrhea is typical of low-grade bile duct obstruction, chronic hepatic disease, mild to moderate pancreatic insufficiency, and even mild celiac disease. Many patients with malabsorption present with symptoms related to a specific vitamin or nutrient deficiency. For example, vitamin A deficiency may cause night blindness, vitamin K deficiency results in easy bruisability, petechiae, or hematuria, vitamin D or calcium malabsorption results in paresthesias, tetany, or bone pain, and decreased absorption of folate, vitamin B, or iron may cause pallor, glossitis, stomatitis, and cheilosis.

The clinician has a broad array of laboratory tests and biopsies to make a diagnosis of malabsorption. The reader is referred to textbooks of gastroenterology for further description of these tests. Radiologic imaging in patients with a clinical diagnosis of malabsorption is performed as an adjunct to help identify diseases (e.g., jejunoileal diverticulosis) that cause malabsorption. Radiologic imaging is also used to detect complications of diseases that cause malabsorption (e.g., T-cell lymphoma arising in celiac disease).

Bacterial Overgrowth

A wide variety of disorders may cause small bowel hypomotility with resulting stasis and bacterial overgrowth (see Box 43-1) or intestinal pseudo-obstruction.

JEJUNOILEAL DIVERTICULOSIS

Small bowel diverticula are acquired protrusions of mucosa and submucosa on the mesenteric border of the small bowel, where the vasa recta pierce the muscularis propria. The diverticula are larger and more numerous in the jejunum, decreasing in size and number as they progress into the ileum.^{8,9} Jejunoileal diverticula develop in a heterogeneous group of disorders associated with abnormalities of smooth muscle or the myenteric plexus. Small bowel dysmotility is frequent. Some cases of jejunoileal diverticulosis may be a manifestation of systemic sclerosis or a forme fruste of isolated scleroderma.¹⁰

Jejunoileal diverticulosis is not uncommon, occurring in about 2% of the population,⁸ but most people with jejunal diverticulosis are asymptomatic. In patients with numerous diverticula, stasis with bacterial overgrowth and malabsorptive symptoms may occur. Complications of jejunal diverticula, including GI obstruction or perforation, may cause abdominal symptoms.

Diverticula are readily identified on barium studies as 1- to 7-cm round, barium-filled sacs on the mesenteric border of the small bowel (Fig. 43-1). The mouths of the diverticula are broad-based and the necks are variable in length. Air-fluid levels may be present on upright or cross-table lateral radiographs. If there are numerous diverticula, the course of the small bowel may be obscured by the numerous sacs. On computed tomography (CT) scans, large diverticula are easily mistaken for small intestinal loops. The best way that diverticula are detected by CT is visualization of an air-fluid level in a focal sacculation.¹¹ The motor disorder seen in jejunoileal diverticulosis is manifested by decreased peristalsis, increased intraluminal fluid and gas, luminal dilation, and prolonged transit time.

Although other small bowel disorders may be associated with sacculations or diverticula, jejunoileal diverticulosis is easily differentiated from the sacculations in Crohn's disease, scleroderma, or prior surgery, a solitary Meckel's diverticulum, or diverticula confined to the terminal ileum.^{1,10}

Jejunoileal diverticulosis may be complicated by pneumatosis cystoides intestinalis or free intraperitoneal air caused by perforation or benign pneumatosis.¹² Jejunal diverticulitis may cause abdominal pain, free perforation obstruction or abscess formation, or GI bleeding.¹²⁻¹⁶ Jejunal diverticulitis is manifested on CT as a stranding or mass in the small bowel mesentery adjacent to a diverticulum or true abscess formation. Mechanical obstruction may result from volvulus, enterolith impaction, or diverticulitis. Heterotopic tissue or neoplasms are rare complications.

Figure 43-1 Jejunoileal diverticulosis causing malabsorption. This overhead radiograph from a small bowel follow-through shows multiple large diverticula on the mesenteric border of jejunum and ileum. The sacs are smooth, but many have a lobulated contour.

PROGRESSIVE SYSTEMIC SCLEROSIS, VISCERAL NEUROPATHIES, AND MYOPATHIES

The small intestine is clinically involved in about 40% of patients with progressive systemic sclerosis (scleroderma).¹⁷ The smooth muscle, especially that of the circular muscle layer, degenerates and is replaced by collagen.¹⁸ The muscular abnormalities result in duodenal and jejunal dilation (Fig. 43-2) and hypomotility, with prolonged small bowel transit time and increased intraluminal fluid. Patchy and predominant fibrosis of the circular muscle layer leads to bunching of small bowel folds, producing the so-called hidebound bowel (see Fig. 43-2).¹⁹ Despite luminal dilation, an increased number of small bowel folds per inch is usually seen. Asymmetric scarring leads to wide-mouthed sacculations, usually on the mesenteric border of the small bowel.^{20,21} As with any small bowel disorder characterized by hypomotility, transient intussusceptions and pneumatosis intestinalis may occur, with or without pneumoperitoneum.

Several forms of visceral myopathies and neuropathies present with malabsorption or intestinal pseudo-obstruction. These include autosomal dominant and recessive conditions or isolated cases.²² Other isolated cases have been caused by Epstein-Barr virus infection or abnormalities of cytoskeleton filament proteins.²³ Visceral myopathies are characterized histologically by degeneration and fibrosis of the inner circular and outer longitudinal smooth muscle layers.²⁴ Congenital neuropathies are characterized by degeneration of the myenteric plexus

Figure 43-2 Scleroderma. This spot radiograph from enteroclysis shows a massively dilated small bowel. (Compare the diameter of the lumen with the size of a lumbar vertebral body.) There is also an increased number of folds per inch, producing the hidebound sign.

of the bowel. Decreased or absent peristalsis is seen in visceral myopathies and scleroderma, but large-amplitude, nonpropulsive contractions are seen in visceral neuropathies.²⁴ Marked duodenal enlargement typically occurs in visceral myopathies, whereas small bowel dilation may be present in visceral myopathies and neuropathies. The increased number of folds and sacculations typical of scleroderma are not found. The colon demonstrates hypercontractility in visceral neuropathy and dilation and lack of haustration in visceral myopathy.²⁴

Epithelial Cell Damage

CELIAC DISEASE

Celiac disease (gluten-sensitive enteropathy, or celiac sprue) is a chronic immunologic inflammatory disease in which the gliadin fraction of wheat, barley, or rye gluten incites damage to the small bowel mucosa. Removal of wheat products from the diet reverses this mucosal damage. Although the mechanism of celiac disease is not completely understood, it is postulated that there is suspension of normal immune tolerance to foreign food antigens.^{25,26} The gliadin fraction of ingested wheat products stimulates an immune response in the epithelium of the small intestine, leading to mucosal inflammation and destruction. Lymphocytic infiltration may also occur in the stomach (as lymphocytic gastritis) or colon.

Celiac disease occurs in about 1 in 200 whites.²⁵ Most people with celiac disease ignore minor symptoms or are asymptomatic. Celiac disease resulting in severe clinical symptoms is uncommon and is usually encountered in whites, particularly northern Europeans and people from Ireland.²⁶ Children may present with diarrhea, abdominal distention, weight loss, and failure to thrive. Young adults may present with diarrhea, steatorrhea, or infertility. Older adults may present with steatorrhea, anemia, weight loss, or other symptoms. Patients who develop symptoms in adulthood or who develop celiac disease *de novo* in adulthood may present with symptoms related to the malabsorption of specific nutrients such as vitamin A or B₁₂. Bleeding or purpura related to vitamin K deficiency may be present. Aphthous stomatitis, cheilosis, and glossitis are not infrequent. In adults, symptoms in celiac disease may be precipitated by

pregnancy, respiratory therapy, and gastric surgery.²⁷ Gluten-sensitive enteropathy is seen in patients with dermatitis herpetiformis.²⁸ Celiac disease has also been associated with other skin diseases, such as psoriasis, eczema, cutaneous amyloid, and mycosis fungoides.²⁴

The diagnosis of celiac disease can be made when physicians test for serum antibodies associated with celiac disease in patients with minimal GI complaints or indicators of malabsorption, such as vitamin deficiencies. Immunoglobulin A (IgA) and IgG antibodies to gliadin are elevated in 75% to 85% of patients with celiac disease.²⁹ These antibodies may also be elevated in some patients with inflammatory bowel disease or liver disease. Endomysial antibody is also elevated in a large percentage of patients with celiac disease.^{30,31}

The antigen for antiendomysial antibody is tissue transglutaminase (tTG). An enzyme-linked immunosorbent assay (ELISA) test for IgA anti-tTG is reported to have a sensitivity of 90% to 95% for the diagnosis of celiac disease. Other studies have shown less favorable results for antiendomysial antibody.³¹ Some patients with celiac disease have IgA deficiency, so this test will have false-negative results in these patients. Small bowel biopsies and follow-up biopsies after gluten withdrawal are usually required for a definitive diagnosis.³²

Biopsy specimens in celiac disease typically reveal a loss of intestinal villi associated with crypt hyperplasia and infiltration of the lamina propria by plasma cells and lymphocytes (Fig. 43-3).³³ Lesser degrees of villous atrophy may be present, however, ranging from mild villous flattening to partial villous atrophy or a flat mucosa. Because other diseases may cause loss of intestinal villi, biopsy-proven reversal of mucosal changes after gluten withdrawal is essential for confirming this diagnosis. Nevertheless, some patients may develop disease that is refractory to gluten withdrawal.

Radiographic Findings

Although endoscopic or capsular biopsy is required for a definitive diagnosis of celiac disease, enteroclysis may help establish the diagnosis in patients with atypical symptoms.³⁴ Enteroclysis is particularly of value for detecting complications in patients with known celiac disease and a poor response to medical

Figure 43-3 Celiac disease. A. A jejunal resection specimen demonstrates marked flattening and loss of villi (short arrows). The crypts are elongated relative to the height of the villi ("crypt hyperplasia") (double arrow). There is an increased inflammatory infiltrate expanding the lamina propria. The muscularis mucosa (mm), submucosa (sm), circular muscle layer of the muscularis propria (C), longitudinal muscle layer of the muscularis propria (L), and serosa (s-tiny arrow) are identified. (H & E, 40×). **B.** Capsule endoscopy shows villous atrophy of the jejunum.

Figure 43-4 Celiac disease. **A.** This spot radiograph from enteroclysis shows a paucity of folds (two to three folds/inch) in two loops of jejunum (j). However, the folds are of normal thickness. **B.** Coronal reformatted CT scan in another patient show markedly increased small bowel secretions. Note that the ileal folds (red arrow) are larger than jejunal folds (yellow arrow).

therapy or patients with recurrent symptoms despite gluten withdrawal.³⁴⁻³⁶

The radiographic findings in celiac disease reflect the villous atrophy that results in loss of mucosal surface area. This mucosal atrophy is manifested as a decreased number of folds in the proximal jejunum (Fig. 43-4), the portion of the small bowel that is most severely atrophic. Three or fewer folds per inch are present in 75% of adult patients with known or suspected celiac disease.³⁴ Four folds per inch in the proximal jejunum is indeterminate for celiac disease, because the proximal jejunum normally has four to seven folds per inch. The mucosal surface pattern may appear finely reticular in uncomplicated celiac disease, with polygonal radiolucent islands of mucosa surrounded by barium-filled grooves.^{34,35} This radiographic pattern reflects the “mosaic” pattern visualized when celiac mucosa is examined under a dissecting microscope.³⁷ Villous atrophy reveals the underlying groove pattern of the mucosa and crypt openings.

In contrast, ileal folds may be increased in number and thicker than normal in celiac disease, an adaptive response to increase the mucosal surface area of the small bowel.³⁸ This phenomenon has been termed *jejunization of the ileum*. If jejunal or proximal ileal folds are enlarged or nodular, complications such as ulcerative jejunoileitis, lymphoma, or edema related to hypoproteinemia should be suspected.³⁵ Nevertheless, thickened nodular folds and discrete mucosal nodules can be seen in the duodenum in patients with uncomplicated celiac disease (Fig. 43-5), reflecting the effect of gastric acid on atrophic duodenal mucosa, in association with inflammation, Brunner’s gland hyperplasia, and gastric metaplasia.³⁹⁻⁴¹

Enteroclysis is much more accurate than small bowel follow-through studies for evaluating fold patterns and establishing the diagnosis of celiac disease or one of its complications. However, transient intussusceptions occur in 25% of patients with celiac disease, and these intussusceptions are better shown on small bowel follow-throughs.^{42,43} Diffuse hypomotility in celiac disease may also be better shown on small bowel follow-through studies.

Figure 43-5 Duodenitis in celiac disease. This spot radiograph centered on the second and third parts of the duodenum shows thick, nodular folds.

Complications

The major complications of celiac disease include malabsorption refractory to gluten withdrawal, hyposplenism, neuropathy, intestinal ulceration and pneumatosis, lymphadenopathy, the cavitory mesenteric lymph node syndrome, and malignancy.^{35,37,44,45} In patients with known celiac disease, complications are frequently heralded by development of fever, acute

abdominal pain, abdominal distention, weight loss, or steatorrhea, despite adherence to a gluten-free diet. CT and enteroclysis are complementary radiologic tests for the diagnosis of these complications.⁴⁶

Splenic atrophy occurs in one third to one half of patients with celiac disease.⁴⁷⁻⁴⁹ Decreased splenic size correlates with decreased splenic function.⁴⁹ A small spleen may be shown on any radiologic test capable of visualizing the spleen.

Mesenteric and retroperitoneal lymphadenopathy are not uncommon in celiac disease and are usually caused by reactive lymphoid hyperplasia.^{50,51} Mesenteric or retroperitoneal lymphadenopathy can be of low attenuation (Fig. 43-6), reflecting fat deposition in lymph nodes, or of normal attenuation. The cavitary mesenteric lymph node syndrome is a rare, usually fatal disorder, typically occurring in patients with celiac disease or patients with small bowel villous atrophy refractory to a gluten-free diet.⁵²⁻⁵⁴ This condition is characterized by markedly enlarged, cavitary lymph nodes filled with lipid-rich hyaline material. CT may reveal mesenteric or retroperitoneal masses of low attenuation, with or without fat-fluid levels (Fig. 43-7).³⁵

Although numerous malignant tumors have been described in patients with celiac disease, there is definitely an increased incidence of squamous cell carcinoma of the pharynx and esophagus and of adenocarcinoma and lymphoma of the small bowel in these patients.^{24,55-62} Malignant tumors are the most common cause of death in adults with celiac disease.⁵⁹⁻⁶³

Small bowel lymphomas are T-cell lymphomas in patients with celiac disease. These tumors have a 300-fold higher incidence in celiac disease than in the general population and are the most common malignant tumors complicating celiac disease.^{24,57,58} T-cell lymphomas in celiac disease are distinct from typical B-cell small bowel lymphomas. T-cell lymphomas usually involve long segments of bowel. Both T- and B-cell lymphomas may have a multifocal distribution. Unlike most small bowel lymphomas, T-cell lymphoma tumors tend to be located in the jejunum rather than in the ileum.³⁵ T-cell lymphomas are usually manifested on barium studies, and CT and magnetic resonance imaging (MRI) scans (Fig. 43-8) by thickened, nodular folds in long segments of jejunum.³⁵ In some

patients, however, radiographic studies may reveal a cavitary or annular lesion (Fig. 43-9).

Radiologic differentiation of T-cell lymphoma from ulcerative jejunoileitis is not possible. Ulcerative jejunoileitis is an entity in which multiple ulcers develop in the small bowel during the fifth or sixth decade of life.^{64,65} About 75% of these patients have celiac disease or villous atrophy unresponsive to gluten withdrawal.⁴⁶ Patients usually present with fever, abdominal pain, weight loss, or abdominal distention. This entity is complicated by GI bleeding, perforation, or obstruction. Ulceration is most prominent in the jejunum but is also seen in the ileum or colon. Thickened, nodular folds may be present in the

Figure 43-7 Cavitary mesenteric lymph node syndrome. This CT scan shows numerous ovoid masses in the abdomen. The masses have fat and debris levels (arrows). These represent enlarged, cavitary lymph nodes that could be mistaken for loops of small bowel with air-fluid levels. However, the fat and fluid attenuation of the nodes and the lack of opacification by positive oral contrast should suggest the correct diagnosis. (From Rubesin SE, Herlinger H, Saul SH, et al: Adult celiac disease and its complications. *RadioGraphics* 9:1045-1066, 1989.)

Figure 43-6 Lymphadenopathy in celiac disease. This CT scan shows numerous low-attenuation lymph nodes (arrow) in the root of the small bowel mesentery and in the retroperitoneum (r).

Figure 43-9 T-cell lymphoma complicating celiac disease. This spot radiograph from enteroclysis shows a short annular lesion (large arrow) with central ulceration (small arrows) in the jejunum. Note the decreased number of jejunal folds proximal to the lesion because of underlying celiac disease.

Figure 43-10 Ulcerative jejunoileitis complicating celiac disease. This spot radiograph during the early phase of enteroclysis shows a loop of jejunum with moderately thickened, irregular folds (arrows) caused by ulcerative jejunoileitis. Also note a decreased number of normal-sized folds more proximally in the jejunum (J) because of underlying celiac disease. (From Rubesin SE, Herlinger H, Saul SH, et al: *Adult celiac disease and its complications*. RadioGraphics 9:1045–1066, 1989.)

jejunum, mimicking the radiographic appearance of lymphoma (Fig. 43-10). Some cases of ulcerative jejunoileitis may progress to stricture formation (Fig. 43-11).

Small bowel adenocarcinomas are usually annular infiltrating lesions involving the duodenum or jejunum.³⁵ These tumors have a threefold higher incidence in celiac disease than in the general population. They are usually advanced tumors at the time of diagnosis.⁵³

TROPICAL SPRUE

Tropical sprue is a persistent contamination of the small bowel by enteric pathogens that occurs in residents of endemic tropical or subtropical areas such as the Caribbean, southeast Asia, and India. Travelers to endemic areas usually develop tropical sprue only after prolonged visits. The disease is uncommon in children. Patients initially suffer a watery diarrheal illness that may remit or progress to chronic malabsorption. Although unproven, it has been postulated that colonization of the small intestine by toxigenic strains of coliform bacteria causes tropical sprue.⁶⁶ Combined folate and vitamin B₁₂ deficiency in tropical sprue can lead to megaloblastic anemia. In tropical sprue, villous atrophy is partial and crypt hyperplasia is not severe. The histologic changes of tropical sprue are found in the duodenum, jejunum, and ileum, unlike the duodenal and jejunal

Figure 43-11 Strictures in ulcerative jejunoileitis complicating celiac disease. This spot radiograph from enteroclysis shows three short segments of ringlike narrowing (arrows) in the jejunum. (From Rubesin SE, Herlinger H, Saul SH, et al: *Adult celiac disease and its complications*. RadioGraphics 9:1045–1066, 1989.)

changes in celiac disease. Tropical sprue responds to antibiotic and folate therapy.²⁴

Tropical sprue is radiographically distinct from celiac disease. Thickened folds are seen in the jejunum (Fig. 43-12) and even the ileum, in contrast to the normal-sized folds (although decreased in number) in uncomplicated celiac disease.

GIARDIASIS

The protozoan *Giardia lamblia* is a frequent cause of endemic and epidemic diarrhea worldwide. Outbreaks of diarrhea are less frequent in the United States. Rarely, giardiasis is heralded by malabsorptive symptoms.⁶⁷ The protozoan attaches to the mucosal surface of the intestine, causing little damage to the underlying small bowel.³³ Barium studies in patients with giardiasis usually show no abnormalities. In severe cases, thickened folds may be seen in the distal duodenum and proximal jejunum.^{68,69} There may be rapid transit of barium and spasm in the proximal small bowel.^{70,71}

WHIPPLE'S DISEASE

Tropheryma whipplei (formerly called *Tropheryma whippelii*) is a gram-positive bacillus with a thick wall and trilaminar membrane.⁷² This recently cultured (1991) bacterium is responsible for the rare systemic bacterial disease first described by George Whipple in 1907.⁷³ It has been postulated that a defect in monocyte-macrophage function prevents affected individuals from eliminating the Whipple's bacillus.

Figure 43-12 Tropical sprue. This spot radiograph from a small bowel follow-through shows moderately thickened, slightly undulating folds in the jejunum. Unlike celiac disease, the number of folds per inch in the jejunum is normal.

Whipple's disease usually occurs in whites, particularly men, with a male predominance of 6:1.⁷⁴ GI symptoms include bloating, weight loss, and steatorrhea. Extraintestinal manifestations include arthritis, arthralgias, cardiac disease, fever, and multiple central nervous system findings, including dementia and myoclonus. Arthritis is the most common extraintestinal manifestation. These patients typically have a migratory arthritis involving large and small joints. Cardiac involvement is characterized by pericarditis, valvular defects, and congestive heart failure. Peripheral lymphadenopathy is not uncommon.

Whipple's disease is typically manifested on barium studies by thickened, nodular folds, primarily in the distal duodenum and jejunum (Fig. 43-13).⁷⁵ Fine mucosal nodularity is sometimes demonstrated as a result of villous blunting caused by expansion of the lamina propria by lacteals distended with fat and by innumerable macrophages containing digested bacilli.³³

CT may reveal enlarged, low-attenuation lymph nodes in the mesentery and retroperitoneum (see Fig. 43-22).⁷⁶ Fat accumulation in obstructed lymph nodes accounts for this low-attenuation lymphadenopathy. Other causes of low-attenuation mesenteric and retroperitoneal lymphadenopathy include *Mycobacterium avium-intracellulare* infection in patients with AIDS, celiac disease, and metastatic testicular carcinoma.^{35,77,78}

The diagnosis of Whipple's disease is confirmed on biopsy specimens showing a lamina propria packed with periodic acid–Schiff (PAS)-positive macrophages containing gram-positive, acid-fast, negative bacilli.³³ Electron micrography may be performed to verify the diagnosis.

EOSINOPHILIC GASTROENTERITIS

Eosinophilic enteritis is a rare heterogeneous group of disorders characterized by an eosinophilic infiltrate in various organs and various layers of the GI tract. Symptoms depend on the distribution and location of the eosinophilic infiltrate. If the small bowel mucosa and submucosa are infiltrated by eosinophils, mild steatorrhea, protein loss, weight loss, and iron deficiency

Figure 43-13 Whipple's disease. This overhead radiograph from a small bowel follow-through shows thickened, nodular folds in the proximal and mid small bowel.

may occur. Eosinophilic infiltration of the muscularis propria results in gastric outlet obstruction or small bowel obstruction.⁷⁹ Eosinophilic infiltration involving primarily the serosa of the small bowel is rare but can result in eosinophilic ascites.⁸⁰ Eosinophilic enteritis usually develops during the third to sixth decades of life. About 50% of patients have a peripheral eosinophilia or an allergic history (including asthma, hay fever, drug sensitivity, or urticaria). The diagnosis of eosinophilic enteritis requires biopsy confirmation of eosinophilic infiltration of the small bowel wall in the absence of extraintestinal disease or parasitic infection.

Eosinophilic infiltration of the small bowel can involve the jejunum or entire small bowel, is typically patchy, and can be unifocal or multifocal. With the mucosal form of eosinophilic enteritis, barium studies may reveal smooth or nodular, thickened folds perpendicular to the longitudinal axis of the small bowel (Fig. 43-14).^{81,82} Spasm is a frequent finding. Eosinophilic enteritis can mimic the radiographic findings of other diseases causing submucosal bleeding in the small bowel (e.g., ischemia). Concomitant gastric disease is found in about 50% of patients. In these patients, barium studies may reveal antral polyps or thickened, nodular antral folds. Thus, clues to the diagnosis of eosinophilic enteritis include simultaneous involvement of the gastric antrum and small bowel, peripheral eosinophilia, and history of allergic diseases.

AMYLOIDOSIS

Amyloidosis is a group of diseases characterized by the extracellular deposition of insoluble fibrillar proteins with specific histologic staining and characteristic features on electron microscopy. In primary amyloidosis and amyloidosis associated with multiple myeloma, a variable portion of an immunoglobulin light chain is deposited predominantly in the muscular layers of the small bowel. This results in small bowel hypomotility. Primary amyloidosis also affects the tongue, heart, kidneys, blood vessels, nerves, and muscles. In secondary and hereditary forms of amyloidosis, amyloid is primarily deposited in the

mucosa, resulting in malabsorption. Secondary amyloidosis is associated with chronic GI diseases such as Crohn's disease and schistosomiasis and chronic systemic inflammatory diseases such as tuberculosis, rheumatoid arthritis, leprosy, chronic osteomyelitis, and familial Mediterranean fever. Ischemia and infarction can result from amyloid deposition in blood vessels.

Barium studies reveal abnormalities in the small bowel in about 40% of patients with primary amyloidosis, including decreased small bowel motility; transient intussusceptions; thickened, nodular folds; focal ulceration; and, rarely, acute perforation.⁸³⁻⁸⁵ Enteroclysis may reveal a finely granular mucosal surface pattern, reflecting blunting of villi and deposition of amyloid in the lamina propria.^{85,86} Large amyloid deposits in the lamina propria may be manifest by 4- to 10-mm, smooth-surfaced, nodular elevations (Fig. 43-15).⁸⁵ Chronic ischemia and infarction may also be manifested by numerous 3- to 4-mm nodules and by erosions and thickened mucosal folds.⁸⁵ Although ischemic changes are reversible, the fine granularity and submucosal nodules do not respond to therapy.⁸⁵

SHORT GUT SYNDROME

Resection of large lengths of the small intestine results in an acute diarrheal illness and long-term malabsorptive state.⁸⁷ Disease states that lead to extensive small bowel resections include vascular damage from volvulus, superior mesenteric artery embolus, superior mesenteric vein thrombosis, and strangulated hernia, Crohn's disease, radiation enteropathy, and abdominal trauma.⁸⁷ Barium studies are of value for documenting the amount of small intestine remaining (Fig. 43-16) and the presence of residual or recurrent small bowel disease—usually the same disease that necessitated small bowel resection. Barium studies may also reveal postsurgical complications such as adhesions and anastomotic strictures. Other complications include gastric hypersecretion with ulcer formation and renal calculi caused by hyperoxaluria after ileal resection. Ileal resection can also lead to cholelithiasis.

Figure 43-14 Eosinophilic enteritis. This spot radiograph from a small bowel follow-through shows thickened, straight folds (small arrows) in several loops of distal small bowel and an abnormal surface pattern (thick arrow) in the terminal ileum.

Figure 43-15 Amyloidosis involving the small bowel. This spot radiograph from a small bowel follow-through shows smooth, thickened folds (small arrow) caused by edema from low-grade ischemia and focal nodularity (large arrow) caused by amyloid deposits in the submucosa.

Figure 43-16 Short gut syndrome. This overhead radiograph shows a total of only three loops of small bowel from the duodenojejunal junction (D) to the ileocecal valve (I). The small bowel is dilated but not obstructed.

In some patients, portions of the remaining small intestine compensate for the loss of bowel by increasing the thickness and number of folds to increase the absorptive capability of the small bowel.⁸⁸ As a result, barium studies may reveal an increased number of ileal folds and increased fold height and thickness.

Nonformation of Chylomicrons

ABETALIPOPROTEINEMIA

Abetalipoproteinemia is a rare, autosomally transmitted disorder that is heterogeneous at the molecular level.⁸⁹ This disorder is linked to a defect in the microsomal triglyceride transport protein (MTTP).⁸⁹ Triglycerides and cholesterol esters are normally secreted from cells in association with the large, hydrophobic, apolipoprotein B (apoB). MTTP is an enzyme found in the endoplasmic reticulum necessary for the assembly of apoB-containing lipoproteins.⁸⁹ Without functioning MTTP, fats cannot be transported out from the basal membrane of enterocytes. This results in the accumulation of absorbed fats and fat-soluble vitamins within enterocytes. Triglycerides also accumulate in hepatocytes.

Symptoms and age at onset vary, depending on the specific defect in apoB-lipoprotein synthesis. Clinically apparent malabsorption may develop at any time, from infancy to early adulthood. Vitamin E deficiency results in spinocerebellar degeneration and acanthocytosis. Vitamin A deficiency results in retinitis pigmentosa, which typically develops during the second decade of life. Mental retardation may also be present.

Barium studies may reveal moderately thickened, nodular folds in the duodenum and proximal jejunum (Fig. 43-17).⁹⁰ It is difficult to explain the radiographic findings on the basis of the underlying pathology. There is no villous distortion or infiltration of the submucosa in abetalipoproteinemia, only

Figure 43-17 Abetalipoproteinemia. This spot radiograph of small bowel shows mildly thickened, irregular folds, possibly caused by intestinal secretions that prevent barium from adequately coating the mucosal surface because the microscopic pathology does not explain the apparent fold thickening in this condition (Courtesy Hans Herlinger, MD.)

accumulation of fat in enterocytes near the tips of the villi. No fat droplets are seen in the intercellular spaces or lymphatics. It has therefore been postulated that these “thickened folds” on barium studies are an artifact of malabsorption, in which increased secretions prevent barium from adequately coating the mucosa.⁹¹

Lymphatic Obstruction and Lymphangiectasia

Primary intestinal lymphangiectasia results from a congenital abnormality of lymphatic development. Secondary lymphangiectasia results from lymphatic obstruction in the small bowel wall and mesentery because of cardiac failure, retroperitoneal fibrosis, radiation therapy, or mesenteric lymph node involvement by Whipple’s disease, tuberculosis, sarcoidosis, lymphoma, or carcinoid tumor.

Lymphatic obstruction results in abnormal absorption of chylomicrons and fat-soluble vitamins, excessive leakage of lymph into the intestinal lumen, and impaired circulation of enteric lymphocytes. Chylous ascites results from serosal and mesenteric lymphatic obstruction. Blockage of the thoracic duct causes chylous pleural effusions.

In patients with primary lymphangiectasia, symptoms usually develop in older children and young adults. Diarrhea is present in 80% of patients. Steatorrhea is less common, occurring in 20% of patients.⁹² Edema of the extremities and chylous pleural effusions are common. Patients may develop hypogammaglobulinemia, lymphocytopenia (particularly of T lymphocytes), and hypoproteinemia.

Barium studies typically reveal thickened, straight, parallel, relatively smooth folds in the jejunum and ileum (Fig. 43-18).⁹² Disproportionate involvement of the duodenum and jejunum occurs in some patients.⁹³ Dilated lymphatic lacteals may cause villous distention and blunting, manifested radiographically by sharply defined 1-mm nodular radiolucencies in the small bowel (Fig. 43-19). Luminal distention is uncommon. CT may reveal a thickened small bowel wall (Fig. 43-20). In patients with secondary lymphangiectasia, CT may also reveal lymphadenopathy of normal or low attenuation.

Multifactorial Diseases

DIABETES MELLITUS

From 10% to 20% of patients with severe diabetes mellitus have diarrhea without malabsorption.⁹⁴ Steatorrhea, if present, is usually mild. Steatorrhea in patients with diabetes mellitus has a variety of causes, including hypomotility with bacterial overgrowth, pancreatic exocrine insufficiency, malabsorption of bile salts, and abnormal small bowel absorption or secretion. About 4% to 9% of patients with type 1 diabetes have clinical celiac disease related to the HLA-DR31-DQ2 haplotype.³³ The pathogenesis of diabetic malabsorption is uncertain. The proximal vagus nerves and sympathetic nerves of the small bowel show varying demyelination, but the myenteric and submucosal plexi are histologically normal.⁹⁵ As a result, diabetics with symptoms related to the small bowel usually have a severe neuropathy and often also have a nephropathy and retinopathy. Barium studies may reveal small bowel transit that is normal, slow, or rapid. Some patients may have accompanying gastroparesis.

CYSTIC FIBROSIS

Cystic fibrosis is an autosomal recessive disorder caused by a variety of defects in the cystic fibrosis transmembrane conductance regulator gene (*CFTR*) on chromosome 7q32.⁹⁶ At least 1000 mutations have been discovered in this gene, accounting for the wide variation in the severity and presentation of cystic fibrosis. Abnormalities in the *CFTR* gene in epithelial cells

result in abnormal duodenal bicarbonate secretion,⁹⁷ abnormal activity of peptide hydrolases, and abnormal chloride secretion. Loss of pancreatic enzyme secretion and subsequent maldigestion further compound small bowel problems. Malabsorption, if present, is related to bile acid and pancreatic exocrine abnormalities.^{96,98}

Figure 43-19 Lymphangiectasia. This spot radiograph from enteroclysis shows mildly thickened, irregular folds. Tiny mucosal nodules (arrow) are seen in one region because of enlarged, bulbous villi.

Figure 43-18 Lymphangiectasia. This spot radiograph of jejunum from enteroclysis shows smooth, mildly thickened, slightly undulating folds.

Figure 43-20 Lymphangiectasia. This CT scan through the upper pelvis shows diffuse thickening of the small bowel wall in profile (open arrow) and en face (large arrow). Stranding of the small bowel mesentery reflects dilated lymphatics and mild mesenteric lymph node enlargement (small arrows).

Figure 43-21 Cystic fibrosis. This spot radiograph from a small bowel follow-through shows luminal dilation and moderately thickened, straight folds.

Although cystic fibrosis does not cause a small bowel–related malabsorptive syndrome, it does lead to a meconium ileus equivalent, often resulting in a functional distal small bowel obstruction or even intussusception of the distal ileum.^{99,100} The proximal colon and distal small bowel are filled with thick, viscous fecal material. Cystic fibrosis is included in this chapter because folds in the duodenum and mesenteric small bowel may appear thickened (Fig. 43-21).¹⁰¹ The cause of these thickened folds is uncertain. It has been postulated that thick secretions coating the mucosa prevent barium from approaching the epithelial layer, leading to the erroneous impression of thickened folds. Whatever the explanation for thick folds, the possibility of ischemia or another malabsorptive state may erroneously be considered in patients with cystic fibrosis.

Differential Diagnosis of Fold Enlargement in Malabsorption

Small bowel folds are composed of mucosa and submucosa and are therefore enlarged by diseases involving the mucosa and submucosa.⁹¹ Smooth enlargement of folds usually indicates edema, hemorrhage, or inflammation in the lamina propria and submucosa. Tiny nodules (0.5–2 mm) usually indicate villous enlargement by mucosal inflammation, amyloid infiltration, or lacteal obstruction. Gross nodularity of folds usually indicates focal deposition of inflammatory cells, amyloid, or tumor.

Malabsorptive diseases manifested by thickened, smooth folds include giardiasis, lymphangiectasia, tropical sprue, and celiac disease complicated by severe hypoproteinemia. Fold changes in giardiasis and celiac disease occur in the proximal jejunum, whereas lymphangiectasia is more evenly distributed throughout the small bowel. Giardiasis is further characterized

Figure 43-22 Lymphoma as a cause of diffuse nodular fold thickening. This spot radiograph from a small bowel follow-through shows moderately thickened, nodular small bowel folds (thick arrow). Tiny nodules reflect villous enlargement (thin arrow). This radiographic appearance is unusual for non-Hodgkin's lymphoma involving the small bowel but can be seen in T-cell lymphoma complicating celiac disease, Mediterranean lymphoma associated with immunoproliferative small intestinal disease, and lymphoma in patients with AIDS. (Courtesy K. Cho, MD.)

by rapid small bowel transit and spasm. Celiac disease is usually associated with a decreased number of folds per inch.

Malabsorptive diseases manifested by thickened, nodular folds include celiac disease complicated by lymphoma or ulcerative jejunoileitis, Whipple's disease, amyloidosis, eosinophilic enteritis, abetalipoproteinemia, and mastocytosis. Thickened, nodular folds in celiac-related lymphoma or ulcerative jejunoileitis are usually focal and located in the jejunum. There also is a decreased number of folds per inch in 75% of patients with celiac disease. In Whipple's disease and abetalipoproteinemia, the folds are more diffusely abnormal, although jejunal predominance occurs in some patients. Whipple's disease is typically a disease of middle-aged white men, whereas abetalipoproteinemia is a disease with retinitis pigmentosa and spinocerebellar degeneration that develops during the second and third decades of life. Eosinophilic gastroenteritis typically has a multifocal distribution, often associated with ileal predominance and skip areas. About 50% of patients with eosinophilic enteritis have a peripheral eosinophilia or allergic history. Amyloidosis is more diffusely distributed throughout the small bowel. Coarse mucosal deposits (nodules >5 mm) of amyloid may be present. Fine mucosal nodules (enlarged villi caused by dilated lacteals) may also be seen in patients with lymphangiectasia if an optimal radiographic technique is used.

Other diseases of the small bowel may produce thickened, finely nodular folds, but malabsorption is not present. About 50% of patients with mastocytosis have flushing, tachycardia, headaches, and urticaria pigmentosa. Mucosal nodularity is usually multifocal. However, malabsorption is rare in patients with mastocytosis. Some patients with diffuse lymphoma have diffusely thickened, nodular folds in large segments of the small intestine (Fig. 43-22). This radiographic pattern is present in patients with mantle cell lymphoma and Mediterranean lymphoma associated with immunoproliferative small intestinal disease (IPSID).

CHAPTER OUTLINE

Clinical Considerations

Imaging Considerations

Specific Tumors

Adenoma

Gastrointestinal Stromal Tumor

Lipoma

Hemangioma

Uncommon Tumors

Polyposis Syndromes

Familial Adenomatous Polyposis Syndrome

Peutz-Jeghers Syndrome

Cowden's Disease

Cronkhite-Canada Syndrome

Clinical Considerations

Primary neoplasms of the small bowel are uncommon and, although about 40 different histologic types of benign and malignant tumors have been identified, they constitute only 1% to 5% of all gastrointestinal neoplasms.^{1,2} Almost 75% of the tumors found at autopsy are benign, whereas most of the symptomatic tumors and tumors detected at surgery are malignant.¹ Regardless of the relative incidence of benign and malignant small bowel tumors, the low susceptibility of the small bowel to neoplastic transformation is remarkable when one considers its length, total mucosal surface area, and diversity of structural elements.

Benign small bowel tumors are usually discovered in patients between 50 and 80 years of age and occur with equal frequency in men and women. Symptomatic patients may present with abdominal pain and other clinical features of partial or intermittent small bowel obstruction.³ Intussuscepting neoplasms may cause significant intestinal obstruction and benign tumors are involved in most adult cases. Bleeding from benign tumors occurs in 40% to 50% of symptomatic patients.³⁻⁵ Anemia, occult bleeding, or intermittent gastrointestinal (GI) hemorrhage may be caused by ulceration of an epithelial adenoma or the mucosa overlying an intramural tumor. In clinical investigations in which enteroclysis was used to evaluate GI bleeding, small bowel neoplasms accounted for 50% of the diagnostic findings, with an almost equal detection of benign and malignant tumors.^{6,7} Constitutional symptoms such as malaise, anorexia, and weight loss are uncommon in patients with benign small bowel neoplasms, as is the ability to palpate the tumor on clinical examination.

Imaging Considerations

Diagnosis of benign small bowel neoplasms remains a dilemma because of the vagueness and paucity of symptoms as well as the difficulty in detecting these lesions on conventional radiologic studies. Because benign small bowel neoplasms are relatively uncommon, most radiologists do not have adequate experience with these tumors, so delayed or inaccurate diagnosis is common.¹⁻⁵ More sophisticated diagnostic methods of intestinal evaluation in patients suspected of small bowel neoplastic disease have been advocated.⁸

Barium-based methods of enteroclysis have been shown to be a reliable technique for the demonstration of small bowel tumors and the evaluation of occult GI bleeding and intestinal obstruction.⁸⁻¹⁰ Enteroclysis may also allow for accurate differentiation of detected benign small bowel tumors.⁹⁻¹¹ Computed tomography (CT) has now become the most readily available and commonly used imaging modality for the evaluation of patients with nonspecific abdominal symptoms. CT has the advantage of demonstrating intraluminal, mural, and extraintestinal abnormalities simultaneously. Certain CT findings can differentiate benign and malignant small bowel tumors and, for some benign tumors such as lipomas and leiomyomas, may allow for a specific diagnosis.¹¹⁻¹³ CT enteroclysis further improves the advantages inherent in multidetector CT (MDCT) scanners by using techniques of small bowel infusion via an enteric tube.^{14,15} Whether performed with positive enteral contrast media (e.g., iodinated, water-soluble) or preferably with neutral enteral contrast media (e.g., water) with intravenous (IV) contrast enhancement, CT enteroclysis has been shown to be an accurate method for the diagnosis of small bowel neoplasms, with a reported sensitivity and specificity of 85% and 97%, respectively.¹⁶ CT enterography, an enteric CT study without intubated intestinal infusion, is an alternative to CT enteroclysis for the investigation of small bowel neoplasms.¹⁷

CT enterography is dependent on the patient's ability to ingest a sufficient volume of oral contrast over a short period of time and interindividual variation in bowel transit time. The choice between the intubation-infusion method (enteroclysis) and oral approach (enterography) is one of preference and may also depend on the clinical indications, patient population, radiology practice, and diagnostic algorithms used by different centers.¹⁸ Magnetic resonance imaging (MRI) of the small bowel has been advocated because of its superior soft tissue contrast resolution, which allows for the differentiation of various pathologic changes in the bowel wall, multiplanar imaging capability, lack of associated exposure to ionizing radiation, possibility of repeated serial acquisitions, and elimination of the need for an iodinated contrast medium.¹⁹ Small bowel capsule endoscopy, although a sensitive technique for the detection of mucosal disease, including intestinal polyposis, has been shown to have limitations in the diagnosis of small bowel tumors.²⁰⁻²²

Specific Tumors

Although numerous benign tumors can be found in the small bowel, approximately 90% are adenomas, GI stromal tumors, lipomas, or hemangiomas. Reports of benign tumors arising from almost all mesenchymal cell types have appeared sporadically in the literature.²³ Benign small bowel tumors often display similar morphologic features on imaging studies. Although a specific histologic diagnosis may be difficult, useful diagnostic observations can be made based on the number and location of tumors and on certain radiologic features that differentiate these lesions.

ADENOMA

Adenomas found within the small bowel are benign glandular epithelial neoplasms that are classified similarly to colonic adenomas and may exhibit a malignant predisposition. Approximately 40% are villous adenomas, and the remainder show a tubular or tubulovillous morphology. As with colonic adenomas, the finding of cellular atypia, a villous component, or large size increases the risk for malignancy. Most patients with adenomas are asymptomatic, but they may occasionally present with GI bleeding or intestinal obstruction secondary to intussusception.

Most adenomas are small (1-2 cm) and have smooth or slightly lobulated contours. They may appear on barium studies as sessile or pedunculated intraluminal polyps or as small mural nodules on enteroclysis (Fig. 44-1). Radiologic differentiation from other polypoid lesions, such as polypoid carcinoma, hamartomatous or inflammatory polyp, or other small submucosal neoplasms, is difficult.

Although small bowel adenomas usually occur as solitary lesions, multiple lesions may be found as a manifestation of hereditary multiple polyposis syndromes (e.g., familial adenomatous polyposis syndrome, Gardner's syndrome).¹ Villous

adenomas are sessile and lobulated, usually larger than most adenomatous polyps, have a strong predilection for the duodenum, and carry a higher risk for malignant transformation (Fig. 44-2).²⁴

GASTROINTESTINAL STROMAL TUMOR

Gastrointestinal stromal tumors (GISTs) constitute a major subset of GI mesenchymal neoplasms and are characterized immunohistologically by the expression of c-kit protein (CD117).^{25,26} These are typically single, firm, circumscribed neoplasms, usually found in the stomach and small bowel.^{2,3,26} GI bleeding, obstruction from intraluminal growth and compression or intussusception are common clinical manifestations.

In reported preoperative series of patients with small bowel tumors, features on barium enteroclysis allowed for the accurate preoperative diagnosis of GISTs in 83% to 100% of patients.^{10,27} Submucosal tumors appear as smooth, round, or semilunar mural defects that are demarcated by sharp angles with the intestinal wall (Fig. 44-3).

CT is particularly useful in depicting the nature and extent of small bowel GISTs.²⁸ These tumors appear on CT as sharply defined masses that display a homogeneous soft tissue density and uniform contrast enhancement. It is difficult to predict the malignant potential of these tumors by imaging alone; however, experience with CT suggests that malignant GISTs are larger than benign tumors, less uniform in shape, and of heterogeneous tissue attenuation.²⁸ A more detailed discussion of GISTs can be found in Chapter 45.

LIPOMA

Lipomas of the small bowel account for 20% to 25% of all GI lipomas, and the small bowel represents the second most

Figure 44-1 Adenoma. Enteroclysis shows a small (8-mm) jejunal adenoma appearing as a smooth, sessile mucosal nodule (arrow).

Figure 44-2 Tubulovillous adenoma. Enteroclysis shows an elongated jejunal tubulovillous adenoma (arrows).

Figure 44-3 Gastrointestinal stromal tumor (GIST). **A.** The submucosal nature of the tumor is recognized on barium study by an area of semicircular mass effect on the lumen (arrows). The smooth surface results from stretching of the normal overlying mucosa. **B.** CT scan of the GIST (L) shows a smooth submucosal mass of homogeneous soft tissue (muscle) attenuation compressing the lumen (arrows).

Figure 44-4 Intussusception of a lipoma. A dilated small bowel loop shows an abrupt narrowing of its lumen at the entry into the intussusception (black arrow). Also note the stretched coil spring pattern of folds typical of intussusception. The contour of the lipoma is visible at the apex of the intussusception (white arrows).

common site for the occurrence of GI lipomas.²⁹ These benign neoplasms arise as a well-circumscribed submucosal proliferation of fat that usually grows intraluminally; outward extension tends to be impeded by the firmness of the muscularis propria. Small bowel lipomas are usually solitary, relatively avascular lesions of variable size (1-6 cm). Most of these tumors occur in the ileum. Although most patients with lipomas are asymptomatic, some may present with intermittent intestinal obstruction, possibly secondary to intussusception (Fig. 44-4).

Figure 44-5 Lipoma. This CT scan shows a lipoma protruding into the bowel lumen (arrow). A well-circumscribed, intraluminal homogenous mass of negative attenuation consistent with fat is characteristic of an enteric lipoma on CT.

Barium studies demonstrate a sharply demarcated, often pedunculated tumor that tends to conform to the contour of the small bowel lumen.^{29,30} The configuration of the tumor may change during fluoroscopy with compression or peristalsis of the small bowel. CT can be diagnostic of small bowel lipoma by showing that the lesion has attenuation values consistent with those of fat³⁰ (Fig. 44-5). The presence of soft tissue stranding within an otherwise uniform lipoma on CT has been attributed to fibrovascular changes associated with ulceration of the tumor.³⁰

HEMANGIOMA

Benign angiomatous tumors are hamartomatous vascular growths, which are most likely congenital. Two principal forms are described—papillary (capillary) hemangiomas and cavernous hemangiomas. Cavernous hemangiomas predominate in the small bowel, occurring as simple polypoid tumors or, rarely,

as diffusely expansile lesions.³¹ Microscopically, these submucosal neoplasms consist of enlarged vascular channels or sinuses lined by endothelium and surrounded by minimal stromal tissue. Hemangiomas may be single or multiple. Although most hemangiomas are only millimeters in size, some may enlarge and protrude into the lumen. Direct invasion of the mucosa or penetration beyond the serosa is uncommon.

In contrast to other small bowel tumors, which are less likely to cause symptoms, 80% of patients with hemangiomas are symptomatic. Most of these patients present with GI bleeding that is often acute, severe, and intermittent. Anemia and occult fecal blood loss are also common clinical findings.

Hemangiomas must be of sufficient size to produce an intraluminal or intramural nodular defect on barium studies (Fig. 44-6). Although a rare occurrence, the finding of calcified phleboliths on abdominal radiographs can suggest the diagnosis. When discovered in patients with vascular cutaneous lesions or tuberous sclerosis, Turner's syndrome, or Osler-Weber-Rendu disease, such radiographic findings should increase suspicion for intestinal hemangiomas. Mesenteric arteriography may be performed to demonstrate an intestinal vascular abnormality, but differentiation between small vascular tumors and other vascular malformations is difficult. In one reported case, CT demonstrated a large jejunal hemangioma that appeared as a heterogeneous mass with prominent mesenteric vasculature.³² CT enteroclysis and CT enterography performed with neutral enteral and IV contrast media have the potential to demonstrate a vascular hemangioma, provided that the tumor is of sufficient size and the intestinal lumen is distended enough for optimal mural visualization (Fig. 44-7).¹⁴

Figure 44-6 Hemangioma. Double-contrast enteroclysis demonstrates a 1.5-cm, slightly lobulated mural nodule (arrow) in a patient with occult gastrointestinal bleeding. A hemangioma was confirmed at surgery. (From Maglinte DD, Lappas JC, Kelvin FM, et al: *Small bowel radiography: How, when, and why?* Radiology 163:297–305, 1987.)

UNCOMMON TUMORS

Neurogenic tumors arise from the intramural neural plexus of the small bowel. Neurofibromas are the nerve tumors most frequently encountered and are composed of nerve sheath elements, notably Schwann cells and fibroblasts. Neurofibromas may occur as single tumors or, more commonly, as multiple lesions, with or without systemic neurofibromatosis type 1 (NF1). Although rare in the general population, neural tumors of the small bowel have been reported in 10% to 25% of patients with neurofibromatosis.³³ Symptomatic neurofibromas in NF1 are most common in the jejunum; clinical manifestations vary depending on tumor extent. Mucosal involvement may lead to GI bleeding or obstruction from intussusception or volvulus. Neurofibromas may originate within the intestinal wall, appearing as solitary or discrete multifocal intraluminal or intramural masses. Multiple or diffusely elongated tumors are evident as mural thickening on CT, whereas on barium studies, these tumors create scalloping of the intestinal wall from the intramural and intraluminal components of the neurofibromas.³³ Neurofibromas of mesenteric origin may encroach on adjacent small bowel, producing mass effect on the serosal surface, or may directly infiltrate the intestinal wall, producing focal or diffuse mural thickening and rigidity or submucosal or mucosal masses (Fig. 44-8).

Ganglioneuromas arise from sympathetic ganglia and manifest as focal polypoid lesions, multifocal polyps (ganglioneuromatous polyposis), or diffuse infiltrating lesions (ganglioneuromatosis). Imaging characteristics of these tumors are similar to those seen in the many forms of neurofibromas.³³

Inflammatory fibroid polyps, also referred to as inflammatory pseudotumors, are encountered almost exclusively in the ileum. They are usually solitary and are composed of a vascular fibrous stroma with a diffuse inflammatory infiltrate. Their

Figure 44-7 Cavernous hemangioma by CT. This is a coronal contrast-enhanced CT enteroclysis image of a patient with anemia requiring blood transfusions. There is a 1.3-cm polypoid mass (arrow) in the proximal jejunum that shows brisk enhancement.

Figure 44-8 Plexiform neurofibroma. This CT scan in a 6-year-old boy with neurofibromatosis type 1 shows an elongated soft tissue mass in the right lower quadrant (white arrows) contiguous with multiple segments of small bowel (black arrow). Surgical pathology confirmed infiltration of the small bowel wall into the intermyenteric plexus.

exact cause remains uncertain, but they likely develop as an exuberant response to local intestinal injury.^{10,34} Barium studies demonstrate a nonspecific smooth, rounded mass in the distal small bowel. Affected individuals may occasionally present with obstructive symptoms caused by intussusception of the polyps.³⁴

Myoepithelial hamartoma is a rare developmental tumor consisting of varying amounts of pancreatic tissue, smooth muscle, and epithelial structures. The term *ectopic pancreatic rest* is used to describe these lesions when there is a predominance of pancreatic acinar tissue. Most myoepithelial hamartomas occur in the gastric antrum or duodenum, but some have been reported in the mesenteric small bowel.²³ Myoepithelial hamartomas are small, solitary lesions that appear on barium studies as smooth mural masses with occasional umbilication.

Heterotopic gastric mucosa may occur as an isolated lesion in the mesenteric small bowel or may be associated with malformations such as Meckel's diverticulum or an enteric duplication. Occasionally, barium studies may demonstrate a polypoid (sessile or pedunculated) lesion in the small bowel.

Polyposis Syndromes

FAMILIAL ADENOMATOUS POLYPOSIS SYNDROME

Familial adenomatous polyposis syndrome (FAPS) and its variants (Gardner's syndrome and Turcot's syndrome) are different manifestations of a hereditary disorder caused by a germline mutation of the adenomatous polyposis coli gene.³⁵ Adenomatous polyps in FAPS typically involve the colon but, to a lesser degree, the small bowel may manifest duodenal and jejunoileal adenomas and ileal lymphoid polyps. Of patients with FAPS and duodenal adenomas, 76% were found to have additional adenomas in the proximal jejunum, and 24% had distal jejunal and ileal polyps visualized by capsule endoscopy.³⁶ Isolated adenomas of the distal jejunum or ileum are rare, occurring in

Figure 44-9 Familial adenomatous polyposis syndrome (FAPS). This CT scan from an enteroclysis performed with water-soluble contrast shows multiple polyps (arrows) within the jejunum.

only 3% of FAPS patients.³⁶ Because small bowel polyps in FAPS occur more frequently in those patients with sentinel duodenal adenomas, CT enteroclysis and capsule endoscopy may have an important role for the diagnosis of small bowel disease (Fig. 44-9).^{20,22,36}

Desmoid tumors are benign proliferations of musculoaponeurotic fibrous tissue that are locally aggressive and tend to recur without distant metastasis. Desmoid tumors are reported in 10% of patients with FAPS, with 50% of the tumors being intra-abdominal—85% to 100% of these tumors are confined to the mesentery.³⁷ CT is an ideal imaging method for the demonstration of desmoids, because it can show the extent of tumor invasion within the mesentery and affected small bowel.^{38,39}

PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers syndrome (PJS) is an unusual autosomal dominant disorder with variable penetrance; about 50% of cases are familial and 50% are new mutations. PJS is characterized by GI hamartomatous polyps, mucocutaneous melanotic pigmentation, and a significant risk for developing a variety of malignancies.^{40,41} Patients with PJS present in early life with pigmented macules on the lips, buccal mucosa, and volar surfaces of the hands and feet. Cutaneous lesions often predate the formation of GI polyps, but typically fade during adolescence, with only the buccal lesions persisting into adulthood. Signs of GI polyps may be evident during the second or third decade of life, with GI bleeding or abdominal pain caused by transient small bowel intussusceptions.

Histologically, the polyps in PJS are benign hamartomas containing a proliferative smooth muscle core and lined by normal intestinal epithelium. These polyps are more commonly found in the jejunum than in the ileum, but may also occur in the stomach or colon. Patients with PJS are at increased risk for intestinal and extraintestinal malignancies, including esophageal, gastric, small bowel, colorectal, breast, ovarian, and pancreatic cancers.^{40,41} Most of the reported carcinomas of the GI tract in PJS patients appear to develop from coexisting adenomas rather than from the hamartomas, but a hamartoma-adenoma-carcinoma sequence is suspected in some cases.⁴⁰

Figure 44-10 Peutz-Jeghers syndrome. CT enteroclysis performed with enteral water infusion and IV contrast enhancement shows multiple intraluminal polyps within the jejunum (arrows). The fluid density of the neutral enteral contrast medium is juxtaposed with the enhancing bowel wall, increasing the conspicuity of the tumor.

Barium studies may demonstrate luminal polyps of variable size in the small bowel. Larger polyps (2–3 cm) typically have a lobulated contour. Pedunculated lesions with broad-based attachments may also be found.^{42,43} Diffuse proliferation of intestinal polyps is not typical for PJS because uninvolved small bowel segments usually alternate with other segments containing several hamartomas. PJS polyps may be detected on CT as soft tissue masses within the contrast medium–filled intestinal loops and are exquisitely displayed by CT enteroclysis (Fig. 44-10).⁴⁴

COWDEN'S DISEASE

Cowden's disease, or multiple hamartoma-neoplasia syndrome, is an inherited condition characterized by hamartomas and

other abnormalities of the skin, breast, thyroid gland, and intestinal tract.⁴¹ Of patients with this disease, 80% present with benign dermatologic manifestations that serve as markers, with the most common being facial trichilemmomas, lipomas, and mucocutaneous keratoses. Patients with Cowden's syndrome are at a particularly high risk for developing breast and thyroid cancers.⁴¹ GI polyposis has been reported in 30% to 60% of patients and includes hamartomas indistinguishable from the polyps seen in juvenile polyposis syndrome, lipomatous polyps, and inflammatory polyps.^{41,43} One or more segments of the GI tract, especially the colon, or the entire GI tract may be involved.

In a review of Cowden's disease, the small bowel was found to be involved in 14 of 32 patients.⁴⁵ Enteroclysis may demonstrate multiple polyps that produce a nodular mucosal surface pattern in patients with diffuse involvement of the small bowel.⁴⁵

CRONKHITE-CANADA SYNDROME

Cronkhite-Canada syndrome is characterized by diffuse GI polyposis associated with distinctive clinical findings. Symptoms of abdominal pain, diarrhea, and anorexia precede or occur together with the development of ectodermal changes, including alopecia, hyperpigmentation, and dystrophy of nails. Disease onset is usually gradual, and older adults are primarily affected. Intestinal malabsorption and protein loss can be severe, and the clinical course is potentially fatal. Polyps occur in the stomach and colon in almost all patients, with the small bowel involved in more than 50% of cases. Cronkhite-Canada polyps are inflammatory in nature and consist of dilated cystic interstitial glands, closely resembling the hamartomas of juvenile polyps. Certain patterns of GI involvement have been described on barium studies: (1) diffuse involvement with innumerable small polyps (most common); (2) scattered polyps of various sizes; and (3) sparse involvement with few small polyps.^{46,47} Barium studies may also demonstrate thickened folds and increased luminal secretions in the small bowel because of hypoproteinemia and malabsorption.

Malignant Tumors of the Small Bowel

KUMAR SANDRASEGARAN | CHRISTINE O. MENIAS

CHAPTER OUTLINE

Imaging Small Bowel Neoplasms

Adenocarcinoma

Carcinoid Tumors

Gastrointestinal Stromal Tumors

Lymphoma

Small Bowel Metastases

Summary

Malignant tumors of the small bowel are rare and account for only 3% to 6% of gastrointestinal (GI) tract malignancies. The most common malignancies include adenocarcinomas, carcinoid tumors, GI stromal tumors, lymphomas, and metastases. The diagnosis of a small bowel neoplasm has been an ongoing challenge for radiologists. Despite almost four decades of surgical and technologic advances in diagnostic modalities, the survival of these patients has not changed, largely as a result of delays in clinical diagnosis. In this chapter, we examine the common small bowel malignancies and evaluate how the radiologist may better diagnose these lesions.

The small intestine represents 75% of the length and 90% of the mucosal surface of the GI tract. Despite this large area of exposure to carcinogens, small bowel neoplasm are uncommon and account for only 3% to 6% of GI neoplasms.¹ Possible reasons for the low prevalence of small bowel cancers include rapid transit time reducing mucosal exposure to carcinogens, a high volume of fluid diluting carcinogens, the absence of bacterial degradation of bile salts, a high proliferation rate and apoptosis of mucosal cells, and immunomodulation by high levels of immunoglobulin A produced by the abundant ileal lymphoid tissue.²

Despite advances in diagnostic imaging and operative techniques, the survival of patients with primary malignant tumors has not changed in the last two decades.³ The main reasons for the absence of survival benefit are delayed diagnosis⁴ and lack of novel adjuvant therapies.³ Patients with small bowel neoplasms often present with nonspecific symptoms such as abdominal pain or GI bleeding.¹ Given the relative rarity of small bowel tumors, physicians have a low index of suspicion. The imaging tests ordered initially, such as fluoroscopic studies and routine abdominopelvic CT, have low sensitivity for small bowel neoplasms, which leads to further diagnostic delay. We will discuss general considerations for the imaging of suspected small bowel neoplasms and then examine the five most common small bowel malignancies—adenocarcinoma, carcinoid tumor, GI stromal tumor, lymphoma, and metastatic tumor (Table 45-1). In diagnosing small bowel malignancies,

location in the proximal or distal small bowel is an important differentiating factor.

The growth pattern of small bowel malignancies may be exoenteric or endoenteric. An exoenteric growth pattern is characterized by extension of tumor into the outer layers of the small bowel wall and mesentery without growth into the lumen, although an extrinsic luminal indentation may be seen. In contrast, an endoenteric growth pattern is characterized by tumor confined to the lumen and bowel wall without extension into the adjacent mesentery. Occasionally, a mixed pattern, with a dumbbell appearance, may be seen. Other imaging features such as the presence or absence of adenopathy, mesenteric masses, or bowel obstruction and the vascularity of liver metastases (if any) help narrow the differential diagnosis.

Imaging Small Bowel Neoplasms

When a small bowel neoplasm is suspected, small bowel enteroclysis or small bowel follow-through has traditionally been performed. These studies are relatively insensitive for the diagnosis of malignant small bowel tumors. In various series, abnormalities were present on small bowel follow-through in 53% to 83% of patients with primary malignant small bowel tumors, but direct evidence of tumor was found in only 30% to 44% of patients.⁵ In general, enteroclysis has better accuracy than small bowel follow-through.^{4,6} Nevertheless, a major limitation of enteroclysis is the lack of demonstration of extraintestinal abnormalities.

Techniques that allow for optical visualization of tumors include video capsule endoscopy and double-balloon endoscopy. These techniques are usually performed by GI physicians. Detailed discussions of these techniques have been published.⁷⁻⁹ Capsule endoscopy is now routinely performed for unexplained GI bleeding or suspected small bowel disease. It depicts small bowel mucosa very well (Fig. 45-1) but has many limitations, including lack of visualization of submucosal lesions (Fig. 45-2), limited angle of view, susceptibility to becoming lodged at the site of a stricture, incorrect triangulation of the site of disease, and the need to view several thousand images.⁹ Double-balloon endoscopy allows for sampling of the lesion but is time-consuming and often requires two procedures to evaluate the entire small bowel.^{10,11} This technique has a complication rate of approximately 1.2% to 3.6%, including bowel perforation,¹² has limited availability, and is only used in select cases.

Cross-sectional imaging examinations are not only able to view the mucosa, but also the bowel wall and adjacent mesentery. Dedicated small bowel computed tomography (CT) or magnetic resonance imaging (MRI) techniques may be divided into enteroclysis or enterography procedures. CT enterography has been increasingly used as the first-line investigation in small bowel disease, including Crohn's disease and small bowel neoplasm.¹³ In enterography, 1350 to 2000 mL of enteral contrast is ingested over a period of about 1 hour. In enteroclysis, a tube

Figure 45-1 Capsule endoscopy of proximal jejunum. This shows exquisite anatomic detail with depiction of individual villi. This degree of spatial resolution is not possible with imaging techniques. However, there are multiple pitfalls of capsule endoscopy.

Figure 45-2 Typical findings of gastrointestinal stromal tumor. This 65-year-old man presented with obscure gastrointestinal bleeding. Coronal reformation of CT shows a mildly hypervascular, 4-cm exoenteric mass (arrowhead) in the mid small bowel. This lesion was missed on prior capsule endoscopy (not shown).

TABLE
45-1

Typical Imaging Features of the Four Major Malignant Small Bowel Neoplasms

Neoplasm	Location	Growth Pattern*	Contrast Enhancement	Obstruction†	Other features
Cancer‡	Periampullary, prox. jejunum	Endoenteric	Variable, usually less than mucosa	Common	Apple core, constricting.
Carcinoid	Distal ileum	Endoenteric	Usually intense and homogenous	Rare	Small: often have spiculated mesenteric mass. Hypervascular liver metastases.
NHL	Ileum	Exoenteric	Usually = or > than mucosa	Rare	Often large; may show aneurysmal dilation, often with adenopathy.
GIST	Jejunum	Exoenteric	Usually intense and homogeneous	Rare	Usually no adenopathy. May show liver or mesenteric metastases.

*Endoenteric growth is into lumen of bowel, while exoenteric growth is outward into adjacent mesentery.

†Frequency of small bowel obstruction.

‡Small bowel adenocarcinoma.

GIST, Gastrointestinal stromal tumor; NHL, non-Hodgkin lymphoma; prox., proximal.

is placed in the distal duodenum or proximal jejunum and enteral contrast is mechanically pumped into the small bowel using a dedicated hydraulic pump (preferably) or by hand. In CT enteroclysis and enterography, the optimal enteral contrast is neutral contrast—with a Hounsfield density similar to that of water. Water, methylcellulose, mannitol, polyethylene glycol, and a proprietary preparation of 0.1% barium sulfate suspension (VoLumen, E-Z-EM, New York) are used. It is vital to administer an adequate bolus of intravenous (IV) contrast at a rate of 3 to 5 mL/s. Ideally, scanning should be done in at least two phases to include a late arterial phase (scan time to start, ≈35–50 seconds) and venous phase (70- to 80-second delay from contrast injection). Additional delayed phases may help demonstrate that the high density in the lumen is extravasated blood.

MRI enteroclysis or enterography has different types of enteral contrast; the most commonly used contrast in the United States is 0.1% barium sulfate solution. Antiperistaltic agents are commonly administered. If glucagon is used, it is advisable to give 0.5 mg intramuscularly or subcutaneously at the start of the study and then the same dose again before the GI postcontrast phases.^{14,15} The typical MRI enterography-enteroclysis protocol includes coronal T2-weighted, single-shot fast spin-echo (SSFSE) or coronal half-Fourier acquisition single-shot turbo spin-echo (HASTE), and coronal single-shot free precession sequences (e.g., fast imaging with steady-state precession [FIESTA], fast imaging with steady-state precession [FISP], fast field echo [FFE]). Postcontrast coronal, 3D fat-suppressed gradient echo sequences (e.g., volumetric interpolated breath-hold examination [VIBE], liver acquisition

with volume acceleration [LAVA], T1-weighted high-resolution isotropic volume examination [THRIVE]) need to be acquired in multiple phases, typically starting 35 seconds after gadolinium injection.¹⁵⁻¹⁷

A study of CT enteroclysis reported a sensitivity of 100% for diagnosing small bowel neoplasms ($N=21$).¹⁸ However, because this study did not have a reference standard, such as capsule endoscopy or long-term clinical and radiologic follow-up, it was not possible to ascertain its true sensitivity. A larger study of 219 patients with suspected small bowel neoplasms reported a sensitivity of 85% and specificity of 97% with CT enteroclysis. A prospective MRI enteroclysis study of 150 patients (including 19 with small bowel neoplasms) reported an overall sensitivity and specificity of 86% and 98%, respectively.¹⁹ Another MRI enteroclysis study of 91 patients with suspected small bowel neoplasms found a sensitivity of 91% and 94% for the two blinded reviewers and a specificity of 95% to 97%.¹⁷ It is likely that CT and MRI enteroclysis have a similar accuracy for diagnosing small bowel neoplasms, which is considerably better than that of fluoroscopic studies. CT is faster and better tolerated by ill patients compared with MRI, but has the disadvantage of using ionizing radiation. To our knowledge, there are no prospective or large studies comparing the sensitivity of enteroclysis versus enterography for the diagnosis of small bowel neoplasms. In general, enterography is easier to perform than enteroclysis and is the preferred diagnostic option in most centers.

Adenocarcinoma

The incidence of small bowel adenocarcinoma increased from 5.7/million in 1974 to 7.3/million in 2004.²⁰ Excluding periampullary tumors, the distribution is approximately 55% in the duodenum, 15% in the jejunum, and 13% in the ileum. There is a distal ileal preference in patients with Crohn's disease. Tumors in the jejunum have a significantly better survival than those in the ileum.³

Adenocarcinoma of the small bowel has risk factors similar to those of colon cancer. Small bowel adenocarcinoma is associated with familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). The

generally accepted hypothesis is that adenocarcinoma occurs via an adenoma-carcinoma sequence and that there are mutations in key regulatory genes, such as *p53* and *k-ras*, in a manner similar to that for colon cancer.²⁰ Other risk factors include Crohn's disease and celiac disease.

Small bowel adenocarcinoma typically presents as an annular, constricting mass (Fig. 45-3). Less common radiographic features of small bowel adenocarcinoma include a polypoid or ulcerated mass or multiple filling defects. The tumors show heterogeneous enhancement on CT and MRI. Differentiation from active inflammation is important in diagnosing adenocarcinoma in the setting of Crohn's disease. Features that support the presence of malignancy include lack of mural stratification, asymmetric wall thickening, and a lobulated outer wall surface (Fig. 45-4). Mesenteric vascular congestion is unlikely to be seen in malignancy, unless there is coexisting inflammation. Surgery is the mainstay of treatment for small bowel adenocarcinoma. Adjuvant chemotherapy has been used

Figure 45-3 Typical findings of small bowel adenocarcinoma. Axial CT on a 67-year-old presenting with small bowel obstruction. There is an annular, constricting mass (arrow) in the proximal jejunum, with upstream bowel dilation (arrowhead). The location of this tumor and its imaging findings are characteristic of adenocarcinoma.

Figure 45-4 Diagnosing cancer in Crohn's disease. A, B. Axial CT scans in 41-year-old woman show mild wall thickening in the terminal ileum (white arrowhead). There is mural heterogeneity, with enhancement of the mucosa and edema in the submucosa. More proximally, an 8-cm segment of substantial wall thickening with homogeneous enhancement is seen (black arrowhead). **B.** There is proximal shouldering (black arrowhead). At surgery, Crohn's disease was found in the terminal ileum. The more proximal lesion was an adenocarcinoma. Good bowel distention and an IV contrast bolus are required to diagnose cancer in the presence of inflammatory bowel disease (white arrowhead).

increasingly, although there are no conclusive data that support its benefit²⁰

Carcinoid Tumors

The current term for all carcinoid tumors is *gastroenteropancreatic neuroendocrine tumors*. Surveillance, Epidemiology, and End Results (SEER) database findings on over 67,000 small bowel tumors, recorded over 30 years, have been published. These data show that the incidence of carcinoid tumor increased by 350% from 1974 to 2004.³ Carcinoid tumor is now considered to be the most common primary malignant lesion of the small bowel, with a slightly higher incidence (37.4% of all cases) than small bowel adenocarcinoma (36.9%). The incidence trajectory of carcinoid tumors, most likely the result of improved imaging technique, may widen this gap in the future.

Carcinoid tumors originate from the ectodermal cells of the neural crest and therefore may occur at any site in which these cells are present, including the GI, pancreatic, biliary, respiratory, and genitourinary tracts and the thymus. Approximately 95% of GI carcinoid tumors occur in the appendix, rectum, and small intestine. About 60% of small bowel carcinoid tumors occur within 40 cm of the ileocecal junction. There are no clear histologic differences between benign and malignant carcinoid tumors. All carcinoid tumors are potentially malignant, with the most important factor being the depth of invasion. Small bowel carcinoid tumors are more aggressive than appendiceal or colonic carcinoid tumors, and may show metastases even when small. Generally, tumors smaller than 1 cm are found to have metastasized 50% of the time, whereas tumors larger than 2 cm are found to have metastasized 95% of the time (Fig. 45-5).²¹ Ileal carcinoid tumors usually metastasize to peritoneal surfaces, omentum, lymph nodes, liver, and lungs.

The carcinoid syndrome consists of periodic cutaneous flushing, diarrhea, bronchospasm and, less commonly, valvular stenosis in the right heart. Only 20% of small bowel carcinoid tumors give rise to this syndrome. The liver deaminates serotonin secreted by the tumor into biologically inert 5-hydroxyindoleacetic acid (5-HIAA). Thus, in 85% of patients with carcinoid syndrome, there are hepatic metastases, the secretions from which enter the systemic circulation directly. In some cases, the syndrome may occur in the absence of hepatic metastases if there is liver dysfunction, high tumor load, or retroperitoneal metastases with venous outflow that bypasses the liver.

Small bowel follow-through studies are only about 25% sensitive for carcinoid tumors. Somatostatin receptor nuclear scintigraphy is 70% to 80% sensitive. If a CT examination is also performed, the two techniques have a combined sensitivity of more than 90%. When a tumor is incidentally found in the distal ileum, carcinoid tumor should be the leading consideration. When visible on CT, the primary tumor typically has a smooth, rounded, and intensely enhancing appearance (Figs. 45-5 and 45-6). The desmoplastic reaction caused by the release of vasoactive amines typically causes a spiculated mesenteric mass (see Fig. 45-6). This mass may be calcified in up to 70% of cases.²² Depending on the severity of the desmoplastic reaction, there may be indrawing or fixation of adjacent bowel loops. Liver lesions are best demonstrated on dual-phase CT. Small metastases are typically hypervascular (see Fig. 45-5), whereas larger lesions are heterogeneous, with peripheral hyperdensity. On MRI, carcinoid tumors are isointense to

Figure 45-5 Small bowel carcinoid. Coronal CT reformation in a 59-year-old woman with carcinoid presenting with diarrhea and wheezing shows a 3-cm hypervascular mass in the distal ileum (arrowhead). Despite the small size of the primary lesion, there are multiple hypervascular liver metastases (arrows).

muscle on T1-weighted images and isointense to mildly hyperintense to muscle on T2-weighted images. As with CT, intense enhancement may be seen. Positron emission tomography (PET) using ¹⁸F-fluorodeoxyglucose (FDG) is only 25% to 40% sensitive because well-differentiated carcinoids are hypometabolic. FDG avidity correlates with malignant potential and has prognostic significance. PET with ¹⁸fluorodopa is considered to be more sensitive than FDG PET, but this radiopharmaceutical has not yet been approved by the U.S. Food and Drug Administration (FDA).

Gastrointestinal Stromal Tumors

A gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor arising from the GI tract. It is characterized by the expression of a tyrosine kinase growth factor receptor and a gain-of-function mutation at the KIT receptor.²³ This is significant because the mutation allows for unchecked growth of the tumor and resistance to apoptosis. Like other small bowel tumors, the clinical presentation of GISTs is often nonspecific. Like GI lymphoma, the most common site of GISTs is the stomach (70%), followed by the small bowel (20%). Within the small bowel, GISTs are usually located in the jejunum,²⁴ and 20% to 30% of GISTs are malignant at presentation.^{25,26} Features associated with a poor prognosis include ileal location, tumor

Figure 45-6 Mesenteric mass of small bowel carcinoid. Coronal CT reformation in a 68-year old man with carcinoid syndrome shows a hypervascular terminal ileal endoenteric mass (arrowhead), with an adjacent spiculated mass (arrow) in the mesentery. Spiculated mesenteric masses occur because of a desmoplastic reaction and need not contain tumor cells. Unlike this case, most mesenteric carcinoid lesions show calcification.

Figure 45-7 Ileal gastrointestinal stromal tumor. Coronal CT reformation in 54-year-old woman with obscure GI bleeding shows a 3-cm, intensely enhancing exoenteric mass (arrow) in the distal ileum. Its exoenteric nature made this mass more likely to be a gastrointestinal stromal tumor (GIST) than a carcinoid. Lymphoma is another possibility, but tends to be larger and has more heterogeneous enhancement. A GIST was diagnosed at surgery.

size, and high mitotic activity.²⁵ Tumors smaller than 2 cm are typically confined to the bowel, whereas those larger than 5 cm are usually malignant and have associated metastases.²⁷

Small GISTs (<5 cm) may show intense homogenous enhancement (Fig. 45-7; see Fig. 45-2). Larger GISTs show heterogeneous enhancement with exoenteric growth¹³ containing areas of low attenuation because of central necrosis or high attenuation because of hemorrhage or calcification (Fig. 45-8).^{28,29} Some GISTs may show a mixed growth pattern with endoluminal and exophytic components and a dumbbell shape. GISTs may be missed by techniques that only assess the mucosa, such as barium studies and capsule endoscopy (see Fig. 45-2). Findings that suggest a poor prognosis on CT include size larger than 5 cm, lobulated outline, heterogeneous enhancement, ulceration of tumor, and mesenteric fat infiltration (Fig. 45-9).²⁸⁻³¹

MRI often reveals a heterogeneous signal caused by internal hemorrhage and necrosis. On T1-weighted imaging, GISTs have low or intermediate signal, whereas on T2-weighted sequences, they exhibit heterogeneously high signal intensity. The most common metastases are to the mesentery and liver. Mesenteric metastases often show low density despite the primary tumor being hypervascular (see Fig. 45-9). Liver metastases are typically hypervascular on CT or MRI prior to chemotherapy.²⁹ Unlike adenocarcinoma and lymphoma, lymphatic spread is uncommon with GISTs.^{29,32} If significant adenopathy or lung metastases are present, an alternative diagnosis should be considered.

GISTs are relatively refractory to conventional chemotherapy and to radiotherapy. Surgical resection offers the best hope of cure. In the last 10 years, molecular therapy using tyrosine kinase inhibitors, has been developed. The first such drug was imatinib (Gleevec, Novartis, East Hanover, NJ). Sunitinib (Sutent, Pfizer, New York) and sorafenib (Nexavar, Bayer HealthCare, Wayne, NJ) are now also used as second- and third-line agents. Tyrosine kinase inhibitor drugs induce apoptosis of the tumor and are administered for metastatic disease and for large nonmetastatic primary tumors after surgical resection. Even when the resected specimen has clear margins, between 40% and 90% of patients develop hepatic or mesenteric recurrence, possibly because of microscopic spillage of tumor at the time of surgery.²⁷

After chemotherapy, mesenteric and liver metastases become hypovascular and often completely cystic on CT (Fig. 45-10).³³ As a result, treated metastases may be mistaken for benign liver cysts on CT. Such cystic lesions should not be considered non-viable. One of the first signs of relapse may be a new enhancing focus within a stable-sized cystic metastasis (see Fig. 45-10).³⁴ Given that size changes are not a significant feature of response or relapse of liver metastases being treated with tyrosine kinase inhibitors, Response Evaluation Criteria in Solid Tumors (RECIST) criteria are not predictive of medium-term response. Other response criteria have been suggested that take into account changes in the enhancement pattern of metastases as a guide to therapy response (Table 45-2).³⁵ As yet, these criteria have not been validated in multiple institutions. Radiologists

Figure 45-8 Atypical gastrointestinal stromal tumors. **A.** Axial CT scan in a 52-year-old shows a 5-cm mass (arrow) arising exoenterically from a proximal jejunal loop (black arrowhead). The mass contains a focus of increased density (white arrowhead) caused by hemorrhage. **B, C.** Axial CT scan in 44-year-old with cirrhosis and ascites shows an incidental mass (arrows). There is dense peripheral calcification and central cystic change. A GIST was diagnosed on surgical pathology. These findings are unusual at presentation, but often seen following therapy with imatinib.

Figure 45-9 Assessing prognosis of GIST on CT. This 48-year-old woman had a GIST. **A.** At presentation, axial CT shows an 8-cm heterogeneously enhancing exoenteric mass (arrow) in the mid small bowel. The tumor was resected, and surgical pathology revealed a GIST with a high mitotic rate. **B.** Axial CT performed 4 months later shows interval growth of low-density mesenteric masses (arrowheads).

should also be aware that imatinib causes hypoalbuminemia and ascites, which may be mistaken for tumor progression (see Fig. 45-10).

Lymphoma

GI lymphoma may be primary or secondary. Primary GI lymphoma is diagnosed when the lymphadenopathy is confined to the region of the bowel mass, the peripheral white cell count and bone marrow aspirate are normal, and there is no evidence

of disease in the liver or spleen, mediastinal adenopathy on chest radiographs, and palpable adenopathy. Secondary lymphoma is diagnosed when multiple sites are affected.

In the West, the most common site of primary GI lymphoma is the stomach (40%-75%), followed by the small bowel (20%-30%), ileocecal region (10%-20%), colon (10%), and esophagus (<1%).³⁶ In some parts of the world, such as the Middle East, small bowel lymphoma secondary to immunoproliferative disorder accounts for 70% of GI lymphomas. In the small bowel, the ileum is the most common site (60%-65%) of involvement.

Figure 45-10 Treatment-related changes of GIST metastasis. This 69-year-old woman had a GIST and liver metastasis. **A.** Axial CT shows a metastasis of 10+ cm in the right lobe of the liver (arrows). **B.** Nine months after therapy with imatinib, the liver metastasis (white arrow) is smaller and completely cystic-appearing, without solid elements. It could be mistaken for a benign cyst if the prior examinations are not available. New-onset ascites (black arrow) is present and was misinterpreted by the radiologist as heralding peritoneal metastases. Ascites may be drug-induced and should not be reported as indicating tumor progression in the absence of solid mesenteric nodules. Imatinib is known to cause hypoalbuminemia, and albumin levels are used to determine the efficacy of therapy. The dose of imatinib was reduced because of the presence of moderate hypoalbuminemia. **C.** Axial CT performed 4 months later shows a mural nodule (arrowhead), a finding that indicates recurrent tumor. A new-onset mural nodule may be the only feature of tumor recurrence.

TABLE 45-2 Comparison of RECIST 1.1 and Choi Criteria in Assessing Response of GIST to Chemotherapy

Parameter	RECIST 1.1 Criteria	Choi Criteria
Complete response (CR)	Disappearance of all lesions and no new lesions	
Partial response (PR)	30+% decrease in size from baseline	10+% decrease in size or 15+% decrease in Hounsfield density
Stable disease (SD)	Not CR, PR, PD	
Progressive disease (PD)	20+% increase in size from prior minimum	10+% increase in size New or enlarging tumor nodules

The Choi criteria were developed at the MD Anderson Hospital in Houston. They allow easier diagnosis of partial response because most GISTs show reduction in enhancement prior to reduction in size.

An ileal predominance is also seen with carcinoid tumors, whereas a jejunal predilection is seen with adenocarcinomas and GISTs. Acquired immunodeficiency syndrome (AIDS) is associated with high-grade B-cell lymphoma, and celiac disease is associated with T-cell lymphoma. There is also a slightly increased risk of lymphoma in Crohn's patients following therapy with antitumor necrosis factor.^{37,38} Predictors of a poor

prognosis include T-cell type, high-grade histology, tumor size larger than 10 cm (Fig. 45-11), and tumor perforation.^{39,40}

As with other small bowel malignancies, small bowel lymphoma presents with nonspecific symptoms. Several imaging patterns of small bowel lymphoma have been described. The most common finding is a predominantly homogeneously enhancing exoenteric mass measuring at least 2 cm in diameter (see Fig. 45-11). This is in contrast to carcinoid tumors, in which the primary tumor is endoenteric and usually smaller than 2 cm. Unlike adenocarcinomas, luminal narrowing or bowel obstruction is not a key feature of lymphoma. Unlike GISTs, adjacent moderate- to large-volume lymphadenopathy is often found with lymphoma. Less common findings of small bowel lymphoma include an exophytic mass with ulceration and central necrosis. Luminal enlargement may occur because of infiltration of the myenteric plexus. This finding is called *aneurysmal dilation of bowel* (Fig. 45-12) and may be found in other submucosal neoplasms, including GISTs and melanoma metastases. Lymphomas show a homogeneously low signal on T1-weighted images and heterogeneously high signal on T2-weighted images.

Small bowel lymphoma that is limited to bowel or associated with adjacent adenopathy (stages IE and IIE, respectively) is often treated surgically because of the risk of perforation with chemotherapy (Fig. 45-13). The treatment of widespread

Figure 45-11 Typical primary lymphoma of the small bowel. A 43-year-old with celiac disease presented with abdominal pain and unexplained weight loss. Axial CT shows a large mass (arrowheads) involving a long segment of mid small bowel. This exoenteric mass enhances homogeneously and does not cause proximal obstruction. The history raised suspicion of T-cell non-Hodgkin lymphoma (NHL) of small bowel. The exoenteric growth, long segment involvement, and lack of proximal bowel obstruction are also features of small bowel NHL. The T-cell histology and large tumor size are poor prognostic features.

Figure 45-12 Aneurysmal bowel dilation in lymphoma. This 48-year-old man presented with abdominal pain and anemia. Axial CT shows a 12-cm small bowel mass (arrowhead) with a distended lumen containing oral contrast and gas (black arrow), a finding known as *aneurysmal bowel dilation*. The proximal bowel (white arrow) was unobstructed. This patient had B-cell non-Hodgkin lymphoma.

Figure 45-13 Risk of perforation of small bowel lymphoma with chemotherapy. This 57-year-old woman had anemia. **A.** Coronal reformation at presentation shows extensive mesenteric adenopathy (arrowhead) and a large mass involving the terminal ileum (arrow). The involved bowel showed eccentric wall thickening. The lumen is distended as a result of aneurysmal dilation. The patient was treated with chemotherapy. **B.** Coronal reformation obtained 3 months later because of an acute abdomen shows an extraluminal gas pocket (white arrow). The lateral wall of the ileum was almost nonexistent (black arrow) and had perforated as a result of rapid tumor lysis. Note the marked regression of mesenteric adenopathy (arrowhead).

lymphoma is not standardized. Management decisions may range from “watch and see” for asymptomatic, low-grade follicular lymphoma to combined chemotherapy and rituximab. Rituximab is a chimeric, monoclonal, anti-CD20 antibody that has been shown to be successful against B-cell lymphomas that express CD20 receptors in over 90% of cases. Rituximab may rarely cause an interstitial pneumonitis that can be mistaken on CT for tumor progression or a chest infection.

Small Bowel Metastases

Metastases to the small bowel often occur as an incidental finding in patients with known abdominal carcinomatosis. Metastatic tumor can involve the small bowel via intraperitoneal spread (the most common route of spread), hematogenous dissemination, or lymphatic channels. Hematogenous spread to the small bowel is usually from malignant melanoma or breast or lung cancer. Postmortem studies show that up to 70% of patients with metastatic melanoma have small bowel metastases. As a general rule, cross-sectional imaging studies have a low sensitivity for detecting these metastases.

In patients with known malignancy and small bowel obstruction, the main considerations are adhesions, radiation-induced strictures, and metastases. Adhesions show sharp zones of transitions, usually adjacent to the anterior parietal peritoneum. The presence of nodular defects or focal enhancement favors metastases (Fig. 45-14). Irregular bowel wall thickening of pelvic small bowel loops with a normal thickness of the proximal jejunum favors radiotherapy. However, all these entities have overlapping imaging appearances.

Summary

The diagnosis of small bowel tumors has not significantly improved over the last several years, despite advances in medical and surgical management, the introduction of capsule endoscopy, and refinements in diagnostic imaging. In most cases, capsule endoscopy is superior to imaging techniques for the diagnosis of small bowel mucosal lesions. However, imaging

Figure 45-14 Small bowel metastases causing obstruction.

This 81-year-old man with known malignant melanoma presented with bowel obstruction. Axial CT shows a serosal mass (arrow) in the distal small bowel with upstream bowel dilation (arrowhead). Multiple melanoma metastases were found at surgery.

tests have a complimentary role in diagnosis, primarily by better demonstration of the bowel wall and adjacent mesentery. Dedicated CT and MRI techniques such as enterography or enteroclysis should be used for the diagnosis of suspected small bowel neoplasms rather than small bowel follow-through or barium enteroclysis. Optimal technique requires adequate small bowel distention, multiphasic IV contrast sequences, and multiplanar reformations. Using the location of tumor, size, exoenteric or endoenteric growth pattern, enhancement pattern, and presence or absence of bowel obstruction (see Table 45-1), it is often possible to determine the type of small bowel neoplasm on imaging studies.

Classification of Small Bowel Obstruction

Extrinsic Lesions

Intramural Lesions

Intraluminal Causes

Intussusception

In patients with known or suspected small bowel obstruction, the radiologist is called on to answer the following questions:

- Is the bowel obstructed?
- If so, what is the level of the obstruction?
- What is the cause of the obstruction?
- What is the severity of obstruction?
- Does the patient have a closed loop or simple obstruction (Fig. 46-1)?
- Is the bowel strangulated?
- Are ischemic changes present?
- Is immediate surgery needed, or should a trial of conservative therapy be used?

These questions are very important to answer because clinical findings may be misleading: approximately 88% of patients with partial small bowel obstruction resolve with conservative management within 48 hours; 37% of patients admitted with ischemic small bowel obstruction have a different clinical diagnosis. The preoperative diagnosis of strangulation is made on clinical grounds alone in 48% of patients. The purpose of this chapter is to provide a working classification for radiologic thinking about small bowel obstruction. After a description of the causes of small bowel obstruction, this chapter will present a radiologic approach to suspected small bowel obstruction (Box 46-1).

Terms Used in Describing Small Bowel Obstruction and Adynamic Ileus

Small bowel obstruction is a condition, not a disease. The term *small bowel obstruction* does not indicate the cause, severity, or

prognosis of the obstruction. The term *ileus* comes from the Greek variably meaning “to twist up,” “to wrap,” or “to roll up,”¹ implying that a patient is rolled up in discomfort. The term *ileus* means that the bowel lumen is dilated, but must have a qualifier before it that indicates neuromuscular-based dilation or mechanical obstruction. *Functional ileus*, *paralytic ileus*, *functional obstruction*, and *adynamic ileus* are equivalent terms indicating that the bowel is dilated because there is abnormal intestinal motility that prevents succus entericus from progressing down the gastrointestinal (GI) tract. Common causes of adynamic ileus include drugs that alter bowel motility (e.g., narcotics), recent abdominal surgery, intestinal ischemia, peritonitis, neuromuscular disorders (e.g., scleroderma), and endocrine disturbances (e.g., diabetes, hypothyroidism). If succus entericus cannot progress down the small bowel because the lumen is mechanically obstructed, the terms *small bowel obstruction*, *mechanical ileus*, or *mechanical obstruction* can be used. To avoid confusion, we will only use two distinct terms—*adynamic ileus* and *small bowel obstruction*.

Simple obstruction implies that the lumen is partially or completely occluded, but that blood flow is preserved. Strangulation or strangulated obstruction means that blood flow is compromised, leading to bowel wall edema, intestinal ischemia and, eventually, necrosis to perforation. A simple obstruction can be complete (i.e., no fluid or gas passes beyond the site of obstruction) or incomplete (i.e., some fluid and gas does pass beyond the site of obstruction). In open loop obstruction, intestinal flow is blocked distally, but the proximal loops are open and can be decompressed by vomiting or nasogastric intubation. In closed loop obstruction, both flow into and flow out of the closed loop are blocked, resulting in progressive accumulation of fluid in the closed loop (see Fig. 46-1).

Pathophysiology

After food has been digested in the stomach and duodenum, most of the contents entering the jejunum are in fluid state. If the neuromuscular function of the bowel is preserved, a large degree of luminal narrowing is needed to cause obstruction. Narrowing can be caused by abrupt angulation, kinking, or compression of the lumen by extrinsic disease; circumferential compromise of the lumen by intrinsic disease, intussusception, and/or obturation by intraluminal contents.

A series of physiologic factors leads to progressive accumulation of fluid in obstructed small bowel loops. Elevated intraluminal pressures stimulate secretion of water and electrolytes into the lumen.² Release of hormones such as vasoactive intestinal polypeptide (VIP) and various prostaglandins stimulates epithelial secretion and inhibits fluid resorption.³⁻⁵ Enzymatic breakdown of intraluminal contents increases the osmolality of intraluminal contents, also drawing more fluid into the lumen.

Intraluminal pressures are higher with closed loop than with open loop obstruction,² which leads to even further secretion

Figure 46-1 Simple versus closed loop small bowel obstruction.

In simple small bowel obstruction (**Simple**), there is a single discordance of small bowel caliber at the transition point (TP). There is tapering of the distention back to the ligament of Treitz (Lig of Treitz). In closed loop obstruction (**Closed loop**), the obstructed segment of bowel between the first transition point (TP A) and second transition point (TP B) becomes markedly dilated and is at risk for ischemia. There is tapering of the distention back to the ligament of Treitz proximal to TP A. The bowel is collapsed beyond the level of TP B. The degree of bowel caliber is triply discordant, most dilated between TP A and TP B, less dilated proximal to TP A, and collapsed beyond TP B. IC valve, ileocecal valve.

of fluid into the closed loop. High intraluminal pressures eventually exceed venous pressures and then capillary pressures. Loss of blood flow leads to the potential cascade of edema, small bowel ischemia, necrosis, and perforation. Stasis in a closed loop obstruction also leads to bacterial overgrowth. Subsequent bacterial invasion of the bowel leads to further edema and inflammation. Release of bacterial toxins into the circulation causes shock.²

In simple (open loop obstruction) of the proximal small intestine, vomiting or intubation leads to the loss of gastric, pancreatic, and biliary secretions. Loss of electrolytes in these secretions results in dehydration, metabolic alkalosis, hyponatremia, hypokalemia, and hyponatremia. Only minor changes in fluids and electrolytes are seen with open loop obstruction involving the distal small intestine because less fluid is lost.

Symptoms

Open loop (simple) obstruction of the proximal small bowel is characterized by frequent, large-volume, often bilious vomiting.² Abdominal pain is intense, but is often relieved by vomiting. Abdominal distention and tenderness are minimal because the small bowel is decompressed by vomiting.

In open loop (simple) obstruction of the distal small bowel, fluid fills the distensible small bowel loops. As a result, vomiting is infrequent and of low volume. Abdominal distention is of moderate to marked degree.

In closed loop obstructions, reflex vomiting may be present, even if the obstruction is distal. Abdominal distention may be absent. Abdominal pain is progressive and may rapidly worsen if ischemia progresses to infarction and perforation.

BOX 46-1 CAUSES OF SMALL BOWEL OBSTRUCTION IN ADULTS

EXTRINSIC LESIONS

- Adhesions
- Hernias
 - External
 - Inguinal
 - Femoral
 - Obturator
 - Sciatic
 - Perineal
 - Supravesical
 - Spigelian
 - Lumbar
 - Incisional
 - Umbilical
 - Internal
 - Paraduodenal
 - Epiploic foramen
 - Diaphragmatic (traumatic)
 - Transomental
 - Transmesenteric
 - Iliac fossa
- Extrinsic tumors in mesentery
 - Lymphoma
 - Peritoneal metastasis
 - Carcinoid
 - Desmoid
- Abscess
 - Diverticulitis
 - Pelvic inflammatory disease
 - Crohn's disease
- Aneurysm
- Hematoma
- Endometriosis
- Congenital
 - Annular pancreas
 - Ladd's bands

INTRAMURAL LESIONS

- Tumors infiltrating wall of small intestine
 - Adenocarcinoma
 - Carcinoid tumor
 - Lymphoma (rare)
 - GI stromal tumors (rare)
- Inflammatory conditions
 - Crohn's disease
 - Tuberculosis
 - Potassium chloride or NSAID-induced stricture
 - Eosinophilic gastroenteritis
- Vascular
 - Radiation enteropathy
 - Ischemia
- Hematoma
 - Post-traumatic hematoma
 - Thrombocytopenia
 - Anticoagulants
 - Henoch-Schönlein purpura
- Congenital
 - Atresia, stricture, stenosis
 - Duplication
 - Meckel's diverticulum

INTRALUMINAL CAUSES

- Obturation
- Gallstone
- Bezoar
- Foreign body
- Ascaris
- Meconium (cystic fibrosis)
- Intussuscepting tumor
- Inverted Meckel's diverticulum

Radiologic Imaging

This section discusses the role of a variety of imaging modalities in patients with small bowel obstruction.

PLAIN RADIOGRAPHY OF THE ABDOMEN

The plain radiograph of the abdomen has traditionally been used as the first radiologic study in the work-up of acute abdominal pain and suspected small bowel obstruction.^{5,6} Many adults admitted with clinical suspicion of acute small bowel obstruction undergo surgery on the basis of clinical, physical, and laboratory findings in conjunction with plain abdominal radiographs. The diagnosis of small bowel obstruction on abdominal radiographs relies on the demonstration of dilated loops of small bowel (**Fig. 46-2**), identified by their smooth luminal contour, valvulae conniventes, and central location in the abdomen. Air-fluid levels may traverse the entire lumen loop of the loop) or be trapped as bubbles between folds at the top of a fluid-filled bowel loop, resulting in a string of pearls sign. Fluid-filled loops may not be seen on supine radiographs but may be recognized on erect or cross-table lateral decubitus radiographs.

Plain abdominal radiographs have only moderate accuracy for the diagnosis of small bowel obstruction. In one series, abdominal radiographs had a sensitivity of 86% for the diagnosis of high grade obstruction, but a sensitivity of only 56% for the diagnosis of low-grade obstruction.⁷ In another series, abdominal radiographs revealed small bowel obstruction in 78% of patients with this condition.⁸ Obstructions can be missed by abdominal radiographs if vomiting or nasogastric intubation leads to decompression of small bowel loops. Fluid-filled loops (**Fig. 46-3**) may not be visible, leading to a false-negative diagnosis or erroneous interpretation of the level of obstruction. In a few patients, abdominal radiographs may be obtained before fluid and air accumulates in the lumen and dilates the small intestine. A false-positive diagnosis of obstruction occurs in up to 44% of patients, mistaking adynamic ileus

or aerophagia for obstruction. The level of obstruction can be accurately predicted in about 75% of patients.⁸

Unfortunately, plain abdominal radiographs are poor at suggesting the diagnosis of strangulation.^{9,10} In patients with strangulating obstruction, the underlying small bowel obstruction is diagnosed in only 50% of patients.^{9,10} Strangulation is suggested on abdominal radiographs by the demonstration of smooth, thick valvulae conniventes in a dilated loop or loops of small intestine. Linear pneumatosis paralleling in the wall of the small bowel or portal venous gas strongly suggests superimposed ischemia and infarction. Closed loop obstructions are often not visible because they are fluid-filled. However, a dilated, fluid-filled loop that does not change location or configuration on serial abdominal radiographs suggests a closed loop obstruction.

COMPUTED TOMOGRAPHY

Given the limitations of plain abdominal radiographs, computed tomography (CT) has become the premier imaging technique for the diagnosis of small bowel obstruction.¹¹ CT has a vital role in these patients because it is readily available, fast, and offers a comprehensive, noninvasive means of assessing the bowel lumen, bowel wall, and adjacent mesentery and vascularity. In comparison to barium studies, CT does not rely on oral contrast reaching the site of obstruction, but uses intestinal fluid proximal to the obstruction to outline the transition zone (see **Fig. 46-3**).¹² As a result, CT has become the imaging modality of choice for diagnosing a variety of conditions, including adynamic ileus, acute or prolonged high grade small bowel obstruction, suspected strangulation or perforation, and acute inflammatory processes such as appendicitis, Crohn's disease, or diverticulitis causing small bowel obstruction. CT is also the best examination for evaluating patients with a known primary tumor and suspected metastatic disease causing small bowel obstruction (**Fig. 46-4**).

CT has an accuracy of almost 90% for the diagnosis high-grade obstructions versus an accuracy of only 50% for low-grade

Figure 46-2 Plain radiographs demonstrating small bowel obstruction. **A.** Plain radiograph obtained with patient in supine position demonstrates diffuse small bowel dilation. **B.** Radiograph obtained with patient standing demonstrates numerous air-fluid levels (arrows).

Figure 46-3 Plain abdominal radiography limitations. **A.** Supine radiograph of the abdomen shows a gasless abdomen. **B.** Coronal reformatted CT scan performed several hours later shows a distal small bowel obstruction with fluid-filled small bowel loops (yellow arrow) and an ischemic jejunal loop (red arrow) with mural thickening. If the bowel is completely filled with fluid, plain abdominal radiographs will misjudge the presence and level of small bowel obstruction.

Figure 46-4 Transition zone with mass demonstrated at CT. Axial CT image through pelvis shows a dilated ileum. There is invasion of the distal ileum by a carcinoma (arrow) of the rectosigmoid junction.

obstructions.⁷ CT can accurately predict the cause of obstruction in 70% to 95% of patients¹²⁻¹⁶ and can often suggest superimposed ischemia and intestinal perforation. The entire abdomen is evaluated by CT, providing a vast array of information not demonstrated by an abdominal radiograph. For example, CT can identify a variety of causes of small bowel obstruction, such as carcinoid tumor, intraperitoneal or hematogenous metastasis, Crohn's disease, appendicitis, and diverticulitis.¹⁷

Although CT is the premier means of evaluating patients with small bowel obstruction, it does have limitations. It is difficult to distinguish an adynamic ileus of the small bowel from a distal small bowel obstruction if a transition zone is not identified.¹⁷ It can also be difficult to determine the location of the transition zone along the course of dilated small bowel, even with the ability to scroll through a scan on a picture archiving and communications system (PACS) workstation or visualize the intestine in any plane. The localization of the transition zone to an abdominal quadrant is not accurate in diagnosing the distance of the obstruction from the duodenal-jejunal junction because a markedly dilated jejunum may fall into the pelvis and an obstructed distal ileum may rotate into the left upper quadrant. Finally, although CT is an excellent technique for suggesting strangulation, it can usually but not always predict whether a bowel loop has reversible or irreversible ischemia or whether the affected small bowel will be viable at surgery.^{18,19} Abnormal bowel wall thickening or mesenteric engorgement also cannot always predict surgical viability of the bowel. In the setting of ischemia, a CT finding of pneumatosis indicates breakdown in the mucosal integrity of the bowel wall and is strongly suggestive of ischemia. The CT finding of pneumatosis can usually but not always predict irreversible ischemia at surgery. Patients with CT findings of free intraperitoneal gas or portomesenteric gas have a greater likelihood of irreversible transmural necrosis than patients with pneumatosis alone. Nevertheless, CT is currently the modality of choice for acutely ill patients with suspected high-grade or complete small bowel obstruction, suspected strangulation, or suspicion of an inflammatory process (e.g., appendicitis, Crohn's disease) or a hernia as the cause of small bowel obstruction.^{20,21}

BARIUM STUDIES

Various barium studies may be performed on patients with suspected small bowel obstruction, including small bowel follow-through, enteroclysis (small bowel enema), barium enema, and studies performed via indwelling nasogastric, nasojejunal, or jejunostomy tubes.

The use of barium is safe in patients with suspected small bowel obstruction because barium does not form concretions in the small bowel lumen proximal to an obstructing lesion. In obstructed patients, the residual fluid in dilated small bowel loops prevents barium from dehydrating and agglomerating. Barium also does not form concretions in the proximal ascending colon. However, concretions may form in the remainder of the colon because water is resorbed from the barium sulfate suspension. Therefore, barium sulfate should not be administered orally or via a proximal bowel tube in a patient with an obstructing lesion distal to the hepatic flexure of the colon because dense barium concretions can form, with the possibility of stercoral ulceration and perforation. If there is any doubt about the location of bowel obstruction, CT or barium enema should be performed before barium is administered proximal to the site of a colonic obstruction.

The presence of barium proximal to a small bowel obstruction makes surgery more hazardous because barium that spills into the peritoneal cavity may result in a form of granulomatous peritonitis. Some surgeons therefore request that small bowel examinations be performed with water-soluble contrast material rather than barium. Small bowel follow-through examinations using water-soluble contrast have even been advocated as a therapeutic technique to improve small bowel obstruction.²²

The use of hypertonic water-soluble contrast in small bowel obstruction can be problematic. This draws fluid into the lumen, whereas the aim of therapy is to decompress the small bowel. Dilution of water-soluble contrast material by retained fluid also may result in very poor radiologic detail, compromising the ability to diagnose small bowel obstruction or demonstrate the site and cause of obstruction. These limitations are partially obviated by the use of iso-osmolar iodinated oral contrast agents.

Small bowel follow-through and enteroclysis studies are not recommended to be performed in patients with high-grade distal small bowel obstruction. Because of small bowel dilation and diminished small bowel peristalsis, it may take an inordinate period of time for barium to reach the site of obstruction. Not infrequently, 24-hour follow-up radiographs must be obtained to visualize the site of a high-grade distal small bowel obstruction. By this time, the barium suspension is diluted and there is poor anatomic detail of the transition zone (Fig. 46-5). The transition zone may even be obscured by dilated-barium filled loops.

If a study must be performed from above in a patient with a high-grade small bowel obstruction, prior passage of a Miller-Abbot tube, Cantor tube, or enteroclysis catheter with a built-in suction port^{23,24} is helpful. The small bowel is first decompressed and then an antegrade barium study is performed.

If more information is needed after CT, a single-contrast barium enema with reflux of barium to the site of small bowel obstruction is often better than an antegrade study in patients with high-grade distal small bowel obstruction (Fig. 46-6). After the administration of 1 mg of intravenous (IV) glucagon to relax the ileocecal valve, barium can be refluxed into the distal ileum in 85% of patients. Barium is then pushed retrogradely by the addition of water to the enema bag. This is an excellent technique that can easily visualize pelvic loops of ileum and even the proximal ileum or distal jejunum. A barium enema is also an excellent technique in patients with an ileocolic anastomosis. A long length of small intestine can be visualized by retrograde flow of barium through the ileocolic anastomosis, resulting in the excellent demonstration of a transition zone. In patients with an ileostomy or colostomy, a retrograde ileostomy or colostomy study can also be performed to diagnose a distal small bowel obstruction.

Enteroclysis and small bowel follow-through examinations are reserved for patients with known or suspected low-grade small bowel obstruction. Enteroclysis should not be performed in patients with high-grade small bowel obstruction, suspected strangulation, suspected perforation, or adynamic ileus. Enteroclysis is superior to small bowel follow-through for the demonstration of short lesions such as strictures or tumors. By overdistending the small bowel lumen, enteroclysis

Figure 46-5 Small bowel follow-through poorly demonstrating transition zone.

A 24-year-old woman had acute abdominal pain and distention.

A. Barium had not reached the colon after 10 hours. An overhead radiograph obtained 24 hours after the ingestion of barium reveals diffuse small bowel dilation. The cecum (c) and ascending colon are relatively collapsed. A gap between the ileum (i) and cecum is minimally filled with barium (arrow). **B.** Axial CT scan through the pelvis demonstrates dilated ileum (l) and thick-walled distal ileum (arrows). Inflammatory stranding surrounds the contrast-filled right external iliac artery. This patient had Crohn's disease.

Figure 46-6 Barium enema demonstrating inguinal hernia as cause of high-grade, small bowel obstruction. The jejunum (J) is dilated. Barium refluxes into the distal ileum (I) and stops at the internal ring of the right inguinal canal (arrow).

can demonstrate subtle adhesions. Obstruction is implied by distention of the jejunal diameter to more than 4 cm and ileal diameter to more than 3 cm. A high-grade obstruction is implied by delayed passage of contrast to the transition zone, dilution of contrast material, and minimal passage of contrast material through the transition zone. A low-grade obstruction is diagnosed if there is delayed passage of contrast at the transition zone itself. Small bowel follow-through examinations are more physiologic, however, with inherent small bowel motility propelling the barium down the intestinal tract, allowing a more accurate estimate of transit time. Small bowel follow-through examinations are also much easier on the patient and examiner, but only in the setting of low-grade or absent small bowel obstruction. Long lesions such as Crohn's disease and ischemia (Fig. 46-7) can be easily demonstrated on small bowel follow-through in patients with low-grade obstruction. Small bowel follow-through examinations (especially with a peroral pneumocolon) are probably superior for the demonstration of the terminal ileum in comparison to enteroclysis.

OTHER STUDIES

CT and magnetic resonance (MR) enteroclysis are intubation techniques discussed in earlier chapters.²⁵ Similar to enteroclysis, these techniques have no role in patients with suspected high-grade small bowel obstruction. These techniques may be of value for patients with carcinoid tumor, radiation therapy,

Figure 46-7 Small bowel follow-through demonstrates low-grade obstruction by ischemic stricture. A 3-cm tapered narrowing (thick arrows) has a small central ulcer (thin arrow) and preserved folds. The jejunum (J) is dilated proximal to the stricture. (From Rubesin SE, Furth EE: *Differential diagnosis of small intestinal abnormalities with radiologic-pathologic explanation*. In Herlinger H, Maglinte DD, Birnbaum BA (eds): *Clinical Imaging of the Small Intestine*, 2nd ed. New York, Springer, 1999, pp 527–566.)

and peritoneal metastasis. Transabdominal ultrasound and conventional MR imaging should be considered as primary imaging modalities for evaluating bowel obstruction only in the pediatric and pregnant population.^{26,27}

Classification of Small Bowel Obstruction

EXTRINSIC LESIONS

Adhesions

Adhesions are the most common cause of small bowel obstruction, accounting for about two thirds of cases.^{28,29} Most adhesions form after abdominal surgery; 10% to 15% of adhesions are attributed to prior or concurrent inflammation.²⁹ A small fraction of adhesions are thought to be congenital in origin. Although adhesions form in more than 90% of patients who have undergone laparotomy, only 5% of patients who have undergone laparotomy will develop an adhesive obstruction.³⁰

About 1% of patients will develop a small bowel obstruction in the immediate postoperative period. About 90% of these early postoperative obstructions are caused by adhesions (Fig. 46-8) and 7% by hernias, with the remainder related to abscess formation, intussusception, or technical factors.^{31,32}

The most important radiographic finding in the diagnosis of small bowel obstruction is the abrupt transition from a

Figure 46-8 Partial small bowel obstruction by an adhesive band. Spot radiograph from an enteroclysis shows a long linear lucency (black arrows), which represents an adhesive band crossing the ileum. The ileum is focally narrowed (white arrow) by the band. Note preservation of small bowel folds (white arrow) in the area of narrowing and dilation of the bowel proximal to the band with collapse of bowel distal to the band.

dilated to nondilated small intestine at the site of obstruction. On barium studies, a sharp, straight, or curved edge (Fig. 46-9) is seen where the adhesive band crosses the bowel lumen. The adhesion itself may be manifest as a narrow, bandlike radiolucency crossing the bowel lumen between dilated proximal and collapsed distal loops. The bowel may be angulated toward the adhesion. Smooth, thin mucosal folds will be tethered toward the extraluminal adhesive process. The bowel may be completely cut off, with a rounded, beaklike, or sharp edge. Mucosal folds are preserved and no mucosal nodularity or mass is present. Several loops may be pulled together at the site of adhesions. Multiple bands or extensive adhesions may be present. Multiple bands are often associated with scar formation along the anterior abdominal wall at prior incision sites. Extensive adhesions are often caused by prior extensive intra-abdominal inflammatory processes, such as traumatic perforation, peritonitis, and postoperative abscesses.

Adhesions are not usually seen on CT. The CT diagnosis of adhesions is a diagnosis of exclusion: there is an abrupt transition from a dilated to collapsed small intestine without apparent cause (Fig. 46-10).³³ The transition zone may appear rounded or beaklike.^{13,34} Other abnormalities can cause a transition zone without apparent cause on CT, including small primary tumors, such as carcinoid tumor, small intraperitoneal metastases, and short inflammatory, ischemic, or drug-related strictures.³³ The CT diagnosis of adhesion is supported by a

Figure 46-9 Adhesion causing complete small bowel obstruction. Abrupt beaklike narrowing (arrow) represents the site of adhesion obstructing the mid small bowel. (Courtesy Hans Herlinger, MD.)

Figure 46-10 Narrowing at site of transition zone. Axial CT scan through the lower abdomen demonstrates dilated small intestine. There is an abrupt transition (arrow) between the collapsed and obstructed small bowel. The small bowel feces sign is present proximal to the obstruction.

history of prior laparotomy in the absence of a history of a tumor with a predilection for peritoneal spread (e.g., ovarian carcinoma) or a known history of inflammatory bowel disease. The CT diagnosis of adhesions is accurate in 70% to 95% of patients.^{7,13-16,35}

Closed Loop Obstruction and Strangulation

The most common causes of closed loop obstruction are single adhesive bands, internal or external hernias, or rents in the mesentery.^{36,37} The trapped loop or loops become progressively dilated and fluid-filled. The vessels feeding the trapped intestine may be compressed by the band or hernia orifice or occluded by twisting of the mesentery; either process results in strangulation. Both dilation and the risk of strangulation of the trapped loops depend on the stage and degree of compression or twisting.

The radiographic findings of strangulation vary, depending on the level of trapping and twisting. Initially, the closed loop may not be dilated. In the usual patient, however, the closed loop is dilated and fluid-filled, with little or no intraluminal gas. If the closed loop(s) are parallel to the plane of reconstruction on CT, they appear as a C- or U-shaped configuration.^{38,39} If the loops are imaged perpendicular to the plane of reconstruction, they appear in a radial configuration, with the trapped mesentery pointing toward the band or hernia orifice (Fig. 46-11). The loops that enter and exit the closed loop lay side by side and are narrowed or tapered at the level of the band or mesenteric rent.⁴⁰ The entry or exit site may have a beaklike appearance when imaged in cross section. The small intestine proximal to the closed loop may be dilated and fluid-filled, whereas the small intestine distal to the closed loop is collapsed. The mesenteric vessels radiate to the point of obstruction.

With a strangulated obstruction, there is a continuum from bowel wall edema to mild to moderate ischemia to transmural infarction and, finally, to perforation. CT has a sensitivity of approximately 90% in the diagnosis of strangulation in a closed loop obstruction.³⁸ CT may reveal circumferential bowel wall thickening of low, normal, or high attenuation. With the use of IV contrast material, wall thickening may show enhancement, delayed enhancement,⁴¹ or no enhancement.⁴² On unenhanced

CT scans, high-attenuation bowel wall thickening implies hemorrhage with ischemia. The lack of contrast enhancement is clear evidence of vascular obstruction.⁴² A mural stratification pattern (target sign), with low attenuation of the submucosa reflecting submucosal edema, may indicate a spectrum of pathology ranging from bowel wall edema to full-thickness infarction. Pneumatosis in the wall of the closed loop indicates a rent in the mucosa and strangulation. A sloughed mucosa or debris in a lumen may have the appearance of feces. CT cannot fully predict viability of the bowel, even if pneumatosis is present.⁴² Air in the mesenteric veins or portal venous system is highly suggestive of nonviable bowel.

If the closed loop is twisted, its mesentery appears twisted or whirled.⁴³ Fluid in the leaves of the small bowel mesentery is not specific for ischemia because intraperitoneal fluid is commonly seen in simple small bowel obstructions. However, strangulation is implied by haziness of the mesenteric fat and large mesenteric vessels, findings reflecting mesenteric edema and venous engorgement, respectively, related to compression or twisting of mesenteric vessels.

Enteroclysis or small bowel follow-through should not be performed in patients with high-grade small bowel obstruction and suspected closed loop obstruction. However, low-grade, potentially partial closed loop obstructions may occasionally be found on barium studies in less symptomatic patients (Fig. 46-12).^{44,45} There is adjacent smooth-surfaced compression of the inflow and outflow limbs as the trapped loops course under the band or through the hernia.^{44,45} Volvulus is implied by twisting of the folds at the point of obstruction. Smooth, thick valvulae conniventes in a partially closed loop imply edema with possible ischemia.

Figure 46-11 Closed loop obstruction caused by transmesenteric internal hernia in a patient with prior Roux-en-Y gastric bypass surgery. Note the markedly distended jejunal segments (red arrows) within the hernia sac, which converge at its orifice (yellow arrow). Ascites is also present.

Figure 46-12 Partial closed loop obstruction demonstrated at enteroclysis. A loop of small bowel is focally dilated. As it enters and exits below an adhesive band, the loop is abruptly angulated and narrowed (arrow), and the folds are pulled toward the small bowel mesentery.

Figure 46-13 CT scan demonstrating Spigelian hernia resulting in closed loop obstruction with strangulation. **A.** Axial image through pelvis demonstrates four loops of intestine (between the *i*), with their mesentery (arrows) radiating toward the midline. Haziness of the small bowel mesentery results from vascular engorgement. **B.** Axial image just caudal to **A** demonstrates the mesentery radiating toward the left anterior abdominal wall (arrowhead). The radially arranged bowel has a thick wall with a mural stratification pattern (black arrow), indicative of minimum submucosal edema caused by ischemia. A loop of intestine is trapped in a Spigelian hernia (large white arrow). The loop exiting the hernia is abruptly angulated (open arrow). The site of volvulus is indicated by the open arrow and arrowhead. At surgery, a twist at the loop exiting the Spigelian hernia resulted in irreversible small bowel ischemia.

Hernias

Hernias occur at predictable sites of weakness in the abdominal wall where there is only fascia and peritoneum between the viscera and skin (Fig. 46-13). A wide variety of internal hernias (Fig. 46-14) occur at sites of mesenteric and omental weakness, normal openings of the peritoneal surface, or under adhesive or congenital bands.⁴⁶⁻⁴⁹ Prior to the era of laparotomy, hernias were the most common cause of small bowel obstruction.

Complications of hernias include incarceration, obstruction, and strangulation. Incarcerated hernias are not reducible, usually because of adhesions in the hernial sac. Urgent treatment is not always required because incarceration is not equivalent to obstruction or strangulation. Incarceration is not a radiologic diagnosis unless the fluoroscopist manually reduces the hernia (indicating that is not incarcerated) or the hernia retracts with change in the patient's position. When incarcerated hernias cause small bowel obstruction, the obstruction is usually high grade or complete.² Strangulation is a serious and life-threatening complication. Strangulated hernias are tense and irreducible.

Inguinal hernias comprise about 80% of anterior abdominal wall hernias; femoral hernias comprise only about 5%.² Inguinal hernias are more common in men than women (7:1), whereas femoral hernias are more common in women than men (1.8:1).² Most patients with an inguinal hernia have a patent processus vaginalis as the cause of the inguinal hernia. These hernias usually result from elevated abdominal pressure related to pregnancy, coughing, constipation, obesity, prostatic, or physical exertion. Inguinal hernias may be caused by weakening of the muscular aponeurosis and fascia because of age, cigarette smoking, or collagen deficiency (e.g., Marfan's, Ehlers-Danlos, and Hunter-Hurler syndromes).²

Direct inguinal hernias occur at Hesselbach's triangle, bounded anterosuperiorly by the inguinal ligament, medially by the rectus abdominis, and laterally by the inferior epigastric vessels that form the lateral umbilical fold. Herniations occur

Figure 46-14 CT scan demonstrating a right paraduodenal internal hernia. There is a cluster of jejunal loops in the hernia sac (arrows) in the right upper quadrant. These loops are poorly perfused, and at surgery irreversible ischemia of the herniated intestine was found.

inferiorly where this region is covered only by peritoneum and the transversalis fascia. Indirect inguinal hernias (Fig. 46-15) occur in the deep inguinal ring in a fossa bounded medially by the inferior epigastric vessels. Because of this anatomy, indirect inguinal hernias are lateral to the inferior epigastric vessels and direct inguinal hernias are medial to the inferior epigastric vessels. Congenital indirect inguinal hernias enter a patent tunica vaginalis. The risk of a major complication in a patient with an inguinal hernia is low.

Weakness in the linea alba at the umbilicus leads to a umbilical or paraumbilical hernia (Fig. 46-16). Most pediatric umbilical hernias close spontaneously, but persistent umbilical hernias require surgery.²

Epigastric hernias also occur in defects in the linea alba. These hernias are more frequent in men. Multiple hernias are seen in 20% of patients. Epigastric hernias usually contain incarcerated preperitoneal fat and do not contain a peritoneal sac. Gastric herniation is uncommon.

Figure 46-15 CT scan demonstrating inguinal hernia. Coronal reformatted image shows a right inguinal hernia (arrow) causing distal ileal obstruction.

Complications in parastomal hernias are uncommon. However, peritoneal herniation develops in more than 50% of patients who have had a colostomy for at least 5 years.

Above the semilunar line (the line of Spiegel), the aponeurosis of each internal oblique muscle splits to surround the rectus abdominis, with its posterior half joining the aponeurosis of the transversus abdominis posterior to the ipsilateral rectus. Below the semilunar line of Spigelius, the aponeuroses of the external and internal oblique muscles and the transversus abdominis pass anterior to the rectus. Spigelian hernias occur below the line of Spiegel, because the junction of the rectus abdominis and lateral flank muscles is weak owing to the lateral abdominal wall muscle aponeurosis passing only anterior to the rectus. A Spigelian hernia is usually small (1 to 2 cm) and intraparietal, rarely penetrating the fascia of the external oblique muscle (Fig. 46-17). Spigelian hernias contain omentum, small bowel, or colon. Incarceration and strangulation are common complications.

A Richter's hernia is a hernia in which only one wall of a bowel loop enters the hernia. The involved wall bowel wall may become ischemic or gangrenous.

The obturator foramen is covered by the obturator internus and externus muscles. The small superolateral corner of the obturator fossa is weakened at the site of penetration by the obturator nerve and vessel. Obturator hernias occur at this superolateral site (Fig. 46-18).

CT and barium studies may reveal smooth, tapered compression of the bowel loops entering and exiting the hernia, with the degree of narrowing determined by the width of the luminal opening (Fig. 46-19).⁵⁰ Dilation of the small bowel proximal to the hernia indicates obstruction at the entry site caused by compression or twisting. Dilation of loops with the hernia itself suggests obstruction at the outflow loop. The radiographic findings of strangulation are similar to those of adhesive obstruction. The sigmoid colon is usually found in a left inguinal hernia and the distal ileum usually enters a right inguinal hernia, although the cecum and appendix can also be pulled into a right inguinal hernia. On barium studies, lateral or steep oblique views are extremely helpful to show midline (Fig. 46-20) or obturator hernias. Upright views or views performed during the Valsalva maneuver are helpful for demonstrating pelvic hernias at fluoroscopy. Similarly, lateral views

Figure 46-16 CT scan demonstrating umbilical hernia resulting in small bowel obstruction and strangulation.

A. Within the umbilical hernia, a loop of small intestine has a thick wall (white arrow). The small bowel is dilated and fluid-filled. The CT equivalent of a string of pearls sign is present (black arrows). The small bowel distal to the obstruction is collapsed (arrowhead). **B.** Axial image just caudal to **A** demonstrates collapsed loops (arrows) entering and exiting the hernia. The fat of the umbilical hernia is engorged. At surgery, the ileum within the hernia sac showed irreversible ischemia.

Figure 46-17 Intraparietal Spigelian hernia. A loop of ileum (large arrow) protrudes just lateral to the left rectus sheath (r). The hernia is intraparietal, covered by the fascia of the external oblique muscle (small arrows).

Figure 46-18 Obturator hernia. Axial CT scan through the pelvis shows a loop of ileum (i) between the pectineus muscle (large arrow) and the external obturator muscle (short arrow). The internal obturator muscle is identified by the arrowhead.

while the patient performs a Valsalva maneuver may enable visualization of anterior abdominal hernias on CT.⁵¹

Extrinsic Tumors in Mesentery or Retroperitoneum

A variety of neoplastic, inflammatory or vascular masses extrinsic to bowel may cause small bowel obstruction. These masses compress the bowel lumen and distort the lumen by a desmoplastic reaction involving the mesentery and peritoneal surfaces of the bowel.

Spread of inflammation from diverticulitis, most frequently sigmoid diverticulitis, can secondarily affect the small bowel. The inflammatory process may cause an adynamic ileus or small bowel obstruction.

Figure 46-19 Right inguinal hernia containing ileum and appendix. Overhead view from barium enema, centered lower than usual, demonstrates ileum (i) below and to the right of the rectal ampulla (R). The tip of the appendix (arrow) enters the right inguinal canal. (From Forbes A, Misiewicz JJ, Compton CC, et al: *Atlas of Clinical Gastroenterology*, 3rd ed. Edinburgh, Elsevier Mosby, 2005.)

Carcinomatosis involving the small bowel mesentery is usually caused by ovarian carcinoma in women and by carcinomas arising from organs adjacent to the peritoneum (including stomach, pancreas, colon, and liver) in men and women. Carcinomatosis is frequently multifocal, occurring at dependent sites in the peritoneal cavity in which ascitic fluid accumulates (including the mesenteric border of the distal ileum, medial base of the cecum, sigmoid mesentery, pararectal fossae, and rectovesical or rectouterine space).⁵² Carcinomatosis produces an extensive desmoplastic reaction, manifested by extrinsic mass effect (Fig. 46-21), angulation of small bowel loops, luminal narrowing, and tethering of folds on both CT or barium studies.^{53,54} CT may demonstrate ascites or peritoneal implants on the surface of the liver, peritoneum, omentum, or mesentery. CT may also reveal the underlying malignant tumor responsible for the ascites. Carcinoid tumors, mycobacterial infection, and desmoid tumors may mimic intraperitoneal metastases. Metastases or lymphoma in retroperitoneal lymph nodes may secondarily infiltrate the small bowel mesentery, causing small bowel obstruction. Retroperitoneal nodal invasion may also resemble intraperitoneal metastases, with mass effect and desmoplastic tethering of the adjacent bowel.

Small carcinoid tumors typically appear as smooth-surfaced, submucosal masses 1 to 2 cm in diameter.⁵³ Once carcinoid tumors infiltrate the deep layers of the small bowel wall or

Figure 46-20 Incisional hernias detected on lateral view. Spot radiograph from small bowel follow-through shows intestinal loops (*large arrows*) protruding through the expected location of the anterior abdominal wall (identified by wire sutures, *small arrow*). Mild, smooth compression of the lower loop with preservation of normal folds (*mid-sized arrow*) is present at the neck of the lower hernia sac.

adjacent mesentery, however, they may be indistinguishable from intraperitoneal metastases on imaging studies. An intense desmoplastic reaction causes focal or multifocal angulation of the bowel wall, luminal narrowing, and tethering of mucosal folds toward the side of mass effect.⁵³ Invasive carcinoid tumors cannot be differentiated on barium studies from intraperitoneal metastases because both disorders are located in the distal ileum and can be multifocal. However, CT demonstration of a large central mesenteric nodal metastasis (with calcification in 50%) is almost diagnostic of carcinoid tumor (Fig. 46-22).⁵⁵

Primary non-Hodgkin's lymphoma of the small bowel does not usually cause obstruction because it is a soft tumor that only narrows the lumen.⁵⁶ However, non-Hodgkin's lymphoma arising in mesenteric lymph nodes or extending from the retroperitoneum into the small bowel mesentery may cause small bowel obstruction because of tumor infiltration and luminal narrowing (Fig. 46-23).⁵⁶

Enteric duplications may compress the small bowel loop and result in obstruction. Duplications typically are located on the mesenteric border of the distal ileum. As a result, barium studies may reveal an extrinsic mass impression on the mesenteric border of the distal ileum. Communication with the lumen of the adjacent small bowel is uncommon. CT typically demon-

Figure 46-21 Intraperitoneal metastases from carcinoid tumor. Spot radiograph of the right lower quadrant from small bowel follow-through demonstrates several areas of extrinsic mass impression and tethering of folds.

strates a mass of soft tissue or fluid attenuation on the mesenteric border of the affected bowel loop.

Slowly leaking aneurysms of the abdominal aorta or iliac vessels or surgery for these aneurysms may also cause a desmoplastic reaction. This can lead to distortion and narrowing of small bowel loops, causing partial or even high-grade small bowel obstruction.

INTRAMURAL LESIONS

Intrinsic tumors or inflammatory processes that infiltrate the submucosa and muscularis propria may cause obstruction by narrowing the lumen of the affected small bowel. A marked amount of circumferential luminal narrowing is necessary to obstruct small bowel because its contents are liquid. Constricting lesions include primary adenocarcinoma, Crohn's disease, and radiation enteropathy. Polypoid lesions of the small intestine may also cause obstruction by intussusception.

Primary Tumors

Adenocarcinoma of the small intestine has a predilection for the second to fourth portions of the duodenum and proximal jejunum. When patients with small bowel adenocarcinoma present with clinical signs of obstruction, these tumors are almost always at an advanced stage. Barium studies may reveal a short annular narrowing, with abrupt, nodular shelflike

margins (Fig. 46-24).⁵³ Nodularity or ulceration may be seen in the center of the lesion. The tumor is rigid and does not change shape with manual compression or peristalsis. A primary tumor may be confused with an annular intraperitoneal metastasis or adhesive band. However, intraperitoneal metastases are located primarily in the distal small bowel, the bowel wall is angulated,

Figure 46-22 Carcinoid tumor causing partial obstruction and ischemia of the ileum. Axial CT scan through the pelvis demonstrates dilated ileum (i) but contrast in the colon, indicative of partial small bowel obstruction. A 2-cm centrally calcified mass (thick arrow) is seen in the root of the small bowel mesentery. Thick strands of tumor radiate from the ileum toward the mass. Two ileal loops (thin arrows) have uniformly thickened walls. At surgery, ischemic changes in the ileum were associated with the carcinoid tumor, which had spread to the root of the small bowel mesentery. (From Rubesin SE: Small bowel tumors. *Contemp Diagnost Radiol* 27:1-6, 2004.)

and the mucosal folds are preserved though spiculated and tethered, rather than nodular (Fig. 46-25).⁵⁷ An adhesive band may circumferentially narrow the lumen, but the mucosa is smooth, and the folds are tethered, not nodular (Fig. 46-26).⁵⁸

Primary lymphoma of small bowel rarely causes obstruction because it is an infiltrative tumor that destroys the muscular wall but does not cause a desmoplastic reaction. Primary lymphoma usually causes focal dilation or cavitation of the small bowel.⁵⁶ Even when primary lymphomas are circumferential and narrow the lumen, high-grade obstruction is unusual because of the soft cellular nature of these tumors.

Inflammatory Conditions

The advanced stenotic phase of Crohn's disease may cause recurrent episodes of partial small bowel obstruction. Although high-grade obstructions are uncommon, small bowel obstruction is the most frequent indication for surgery in patients with Crohn's disease.⁵⁹ When luminal narrowing is seen during barium studies (Fig. 46-27) or CT (Fig. 46-28), the narrowing may be caused by edema, spasm, inflammation, fibrosis or, rarely, a carcinoma. The diameter of the stricture may change during the course of the examination or on delayed images. Severe luminal narrowing has been termed the *string sign*. In such cases, the use of metoclopramide or the high-volume administration of contrast pressure of enteroclysis may distend the lumen to varying degrees, revealing an ulceronodular pattern. Obstruction is diagnosed on barium studies or CT by delayed passage of contrast medium through the diseased segment, with proximal small bowel dilation.⁶⁰⁻⁶² Bowel wall thickening or local mesenteric infiltration do not aid in the CT diagnosis of obstruction. Stenoses that resist the pressure of enteroclysis may require surgery.

Other primary inflammatory causes of small bowel obstruction are rare. Acute infections such as yersiniosis rarely cause

Figure 46-23 Non-Hodgkin's lymphoma secondarily arising in the small bowel mesenteric lymph nodes, partially obstructing the small intestine. **A.** Overhead image from enteroclysis shows that pelvic ileal loops are separated (double arrow) by a presumptive mass in the small bowel mesentery. The small bowel is narrowed, tapered, and partially obstructed at several sites (black arrows). Thick small bowel folds (white arrows) could be the result of ischemia caused by venous or lymphatic obstruction in the mesentery or direct tumor invasion. **B.** CT clarifies the radiographic findings. Separation of bowel loops is caused by a large, homogeneous mesenteric mass (M). A loop of intestine is tapered and partially obstructed (arrow). The tumor circumferentially infiltrates one intestinal loop (open arrow), accounting for the thick folds seen on the enteroclysis. (A from Rubesin SE, Gilchrist AM, Bronner M, et al: Non-Hodgkin lymphoma of the small intestine. *RadioGraphics* 10:985-998, 1990.)

Figure 46-24 Adenocarcinoma of jejunum causing partial small bowel obstruction. **A.** Overhead image from an upper GI series shows a dilated distal duodenum and jejunum (J) proximal to a 3-cm focally ulcerated lesion (arrow). **B.** Spot radiograph shows a circumferential mass (black arrows) with central ulceration (u). This case is an example of how an upper GI series can be converted to a small bowel study when the distal duodenum is dilated.

Figure 46-25 Annular metastasis from colonic carcinoma. Spot radiograph from enteroclysis demonstrates a short annular lesion with a thin lumen (arrowheads). Although the proximal margin is abrupt, the folds are preserved and tethered (arrow).

small bowel obstruction because the acute inflammatory process heals without fibrosis. Tuberculosis is unusual in Western countries but may be seen in returning visitors or immigrants from Asia.⁶³ Tuberculosis may produce radiographic features identical to those of Crohn's disease, but the cecum and ascending colon tend to be more severely involved than the terminal ileum. Patients with tuberculosis may also have a patulous ileocecal valve, rather than the narrowed ileocecal valve typically seen in Crohn's disease. A definitive diagnosis of ileocecal tuberculosis requires culture and biopsy specimens.

Behçet's disease mimics Crohn's disease, but the ulcers are often larger and deeper in Behçet's disease. Focal perforation

Figure 46-26 Circumferential adhesive band. Spot radiograph from enteroclysis shows abrupt angulation (long arrow) at the transition zone. The bowel just distal to the angulation is tight (short arrows), but folds are preserved throughout the region. (Courtesy Hans Herlinger, MD.)

with peritoneal reaction is not uncommon in Behçet's disease. Carcinoma of the cecum and lymphoma of the ileocecal valve invading the terminal ileum may also mimic Crohn's disease.⁵³

Vascular Diseases

Radiation Enteropathy. Radiation enteropathy may cause mild to moderate small bowel obstruction because of a combination of serositis and adhesions, wall fibrosis, and dysmotility. The changes are localized to the preexisting radiation portal, usually

Figure 46-27 Crohn's disease causing partial small bowel obstruction. Spot radiograph from enteroclysis demonstrates a dilated ileum (i) proximal to a 1 cm in length by 1 mm in luminal diameter stricture (long arrow). An ulceronodular pattern (cobblestoning; u) is seen in the ileum distal to the stricture, manifested as transverse and longitudinal barium-filled, knifelike clefts or ulcers (short arrow) separating polygonal islands of relatively spared mucosa. (Courtesy Hans Herlinger, MD.)

Figure 46-28 Crohn's disease causing partial small bowel obstruction. A. Coronal reformatted CT image shows a stricture (arrow) of the midileum, with proximal dilation and the small bowel feces sign.

Figure 46-29 Radiation enteropathy causing low-grade small bowel obstruction. Spot radiograph from enteroclysis shows smooth, thick folds (white arrows) in a deep pelvic ileal loop. The folds are slightly angled, indicating radiation serositis. In profile, the spaces between thick loops have a spikelike appearance (arrowhead), so-called interspace spikes. A nearby loop has top normal-sized folds (black arrow) for comparison.

in the pelvic area. Submucosal edema and fibrosis are manifested on barium studies as smooth, straight, parallel thick folds that cross the small bowel lumen (Fig. 46-29).⁵³ Barium filling compressed interstices between the folds may result in interspace spikes. The lumen of the affected bowel may also be narrowed by submucosal fibrosis. Radiation-induced serositis and adhesions result in fixation and angulation of bowel loops and tethering of folds, similar to any extrinsic adhesive process.⁶⁴ CT may also reveal bowel wall and fold thickening, with submucosal edema demonstrated as a target sign (Fig. 46-30).⁶⁵ Small bowel obstruction caused by radiation serositis is suggested by proximal small bowel dilation associated with angulated loops (see Fig. 46-30B). Adhesive bands may form where the small bowel enters the radiation portal. Smooth, tapered strictures may develop 6 months or more after radiation therapy (Fig. 46-31). Surgery in patients with radiation enteropathy is not without risk because these patients may develop postoperative fistulas and interloop abscesses.²

Blunt abdominal trauma (often a seat belt injury) may result in stricture formation after healing of a bowel wall hematoma or ischemia. However, most hematomas resolve without sequelae after conservative treatment.⁶⁶ Strictures developing at enteroenterostomy sites (Fig. 46-32) may be the sequelae of ischemia, prior leak with fibrotic healing, or surgical technique.

Acute inflammation, ischemia, and ulceration related to the use of nonsteroidal anti-inflammatory drugs (NSAIDs) or potassium chloride tablets may also result in stricture formation.⁶⁷ In these cases, barium studies may reveal ringlike strictures (Fig. 46-33) with tiny central openings.

INTRALUMINAL CAUSES

Gallstones, bezoars, foreign bodies, meconium, and tangles of *Ascaris* worms may obturate the small bowel lumen, causing obstruction.

Figure 46-30 Radiation enteropathy causing low-grade small bowel obstruction. **A.** Axial CT through pelvis shows angulation and wall-thickening (short arrows) of the terminal ileum. In some areas, a mural stratification pattern caused by submucosal edema is evident (long arrow). The cecum (c) is identified. **B.** Spot radiograph from a small bowel follow-through shows angulation of the terminal ileum and smooth thick folds (arrows). The ileum (i) proximal to the radiation change is dilated. .

Figure 46-31 Radiation stricture. A 2-cm long smooth narrowing (open arrows) is present at the edge of the radiation portal. Smooth thick straight folds perpendicular to the longitudinal axis of the bowel (arrows) are typical of radiation change caused by submucosal edema or fibrosis.

Gallstone-induced small bowel obstruction (also known as gallstone ileus) usually occurs in older patients, especially women. A gallstone can erode through the wall of the gallbladder or bile duct into the small bowel or colon. Most fistulas extend from the gallbladder fossa to the duodenum. Passage of

Figure 46-32 High-grade obstruction at enteroenterostomy site. There is a 1- to 2-mm wide, barium-filled, side to side enteroenterostomy (arrows). The jejunum proximal to the obstruction is dilated.

gallstones through the GI tract may result in large gallstones becoming trapped in the narrowest segments of bowel, the terminal ileum and sigmoid colon. Calcified ectopic gallstones are visible on plain radiographs of the abdomen in only approximately 15% of patients. CT is superior for the demonstration of calcified gallstones (Fig. 46-34) as the cause of a small bowel or colonic obstruction.⁶⁸ The classic Rigler's triad of a calcified gallstone, gas in a shrunken gallbladder or biliary tree, and small bowel obstruction is seen in only a minority of patients on plain radiographs,⁶⁹ but is better detected on CT. In some patients, a gallstone may be detected on a small bowel follow-through examination as a calcified or noncalcified intraluminal radiolucent filling defect at the site of transition between dilated and nondilated small bowel.

Foreign body impactions in the small bowel are much less common than foreign body impactions in the pharynx or esophagus.⁷⁰ Small bowel obstruction by foreign bodies usually occurs in psychiatric or mentally challenged patients or in drug smugglers. Some people who eat indigestible food substances, such as persimmons, can develop small bowel bezoars.⁷¹ These patients often have a partial gastrectomy or gastroenterostomy

and may have an underlying obstructive lesion. Cameras used during capsule endoscopy may become stuck behind an obstructing small bowel lesion.

In adults with cystic fibrosis, inspissation of bowel contents may cause small bowel obstruction (meconium ileus equivalent). These patients may have a history of decreased intake of pancreatic enzyme supplements or narcotic use.

INTUSSUSCEPTION

Various extrinsic, intrinsic, and intraluminal processes result in small bowel intussusception. A loop of small intestine with part of its mesentery invaginates into the lumen of the bowel segment distal to it. The inner, advancing segment is termed the *intussusceptum* and the outer receiving segment the *intussusciens*. Most intussusceptions are nonobstructive, transient intussusceptions without a lead point that are detected on abdominal CT performed for other reasons.^{72,73} Nonobstructive transient intussusceptions are also seen in small bowel disorders associated with dysmotility, such as scleroderma or celiac disease. Benign or malignant polypoid tumors are the most common causes of small bowel intussusception in adults presenting with small bowel obstruction.⁷⁴ In postoperative patients, intussusceptions may be related to suture lines, adhesions, or intestinal tubes.⁷⁵

Barium studies typically reveal a narrow, tapered, barium-filled channel outlining the lumen of the intussusceptum (Fig. 46-35).⁵³ If barium refluxes between the outer wall of the

Figure 46-33 Ringlike strictures related to NSAID use. A spot radiograph from enteroclysis demonstrates two ringlike narrowings (arrows) in the jejunum. (Courtesy Arunas Gasparitis, MD, Chicago.)

Figure 46-34 Gallstone ileus. Coronal reformatted CT scan shows an obstructing calcified intraluminal gallstone (arrow).

Figure 46-35 Jejunal intussusception caused by adhesion. The lumen of the intussusceptum is narrow and outlined by barium (long white arrows). Barium refluxes retrogradely between the serosal surface of the intussusceptum and mucosal surface of the intussusciens (thick white arrow). Barium coating the mucosal surface of the intussusciens reveals mucosal folds (short black arrows), the so-called coil spring. At surgery, the intussusception occurred at a site of adhesions.

intussusceptum and mucosal surface of the intussusciens, the mucosal folds of the intussusciens will be demonstrated as parallel folds perpendicular to the longitudinal axis of the bowel. This is the so-called coil spring sign. Coil spring folds that appear thicker than normal small bowel folds indicate that there is mucosal and submucosal edema because of lymphatic or venous congestion. If the intussusception is caused by an underlying tumor, a polypoid lead point may be identified. Barium filling the interstices of the lead point implies that the tumor is a mucosal lesion such as an adenoma or hamartoma. In contrast, a round, smooth-surfaced polypoid lead point suggests a submucosal lesion such as a lipoma or metastatic melanoma.

Small bowel intussusception may be manifested on CT by a pair of concentric rings of soft tissue, with an eccentrically located area of fat attenuation inside the outer ring.^{76,77} The outer ring of soft tissue represents the intussusciens, whereas the inner ring of soft tissue represents the wall of the intussusceptum. The eccentrically located fat represents the mesentery of the intussusceptum (Fig. 46-36). Vessels in the invaginating mesentery may be visible as punctate dots or thin, undulating strands of soft tissue or IV contrast attenuation. If the wall of the intussusciens is thickened, the possibility of bowel wall edema and ischemia should be considered.⁷⁸ Obstruction is implied by dilation of the small bowel proximal to the intussusception associated with collapsed small bowel distally.

The clinical history is helpful for evaluating patients with small bowel intussusception. Most patients with metastatic melanoma as the lead point have a history of prior surgical removal of melanoma from the skin. Some patients with a metastatic, melanoma-related intussusception present with symptoms from the intussusception as the initial manifestation of their disease.⁷⁸ Most patients with Peutz-Jeghers syndrome, an autosomal dominant disorder, have a family history of this syndrome. However, 45% of cases of Peutz-Jeghers syndrome occur as spontaneous mutations, so these patients may initially present with symptoms related to small bowel hamartomas. Most patients with Peutz-Jeghers syndrome have pigmented lesions on the lips, oral mucosa, face, or extremities.⁷⁹ However, pigmented lesions may be overlooked in patients of African or Asian origin; they may present with bleeding or abdominal pain caused by an intussuscepting hamartoma.

The location of the intussusception is of little value in distinguishing between polyps of different histologic types. Peutz-Jeghers polyps and adenomas are usually located in the proximal jejunum, whereas stromal tumors, metastatic melanoma, and lipomas have a relatively uniform distribution in the small bowel.

When small bowel intussusception occurs, barium filling the interstices of a lead point lesion should suggest a tumor of mucosal origin, such as a Peutz-Jeghers polyp or adenoma. Smooth and round but centrally umbilicated or ulcerated

Figure 46-36 Inflammatory fibroid polyp causing intussusception. **A.** Axial CT scan through the pelvis shows the stalk of the polyp (s) within the lumen of the ileum. The mesentery (white arrow) is being pulled into the lumen. **B.** Image just caudal to **A** demonstrates a round, soft tissue attenuation intraluminal mass (f). **C.** Spot radiograph from enteroclysis demonstrates the head of the polyp (F), stalk of the polyp (long black arrow), lumen of the intussusceptum (thin white arrows), serosal surface of the intussusceptum (short black arrow), and retrograde flow of barium into the intussusciens (thick white arrow). (**C** from Rubesin SE: Small bowel tumors. *Contemp Diagnost Radiol* 27:1–6, 2004.)

Figure 46-37 Ileal lipoma causing ileocolic intussusception. Coronal reformatted image shows an intussuscepted fat density lipoma (yellow arrow) causing dilation of the distal ileum (red arrow).

polypoid lead point lesions are usually submucosal tumors, such as stromal tumors or metastatic melanoma. Melanoma metastases have central umbilication or ulceration in more than 50% of patients.⁸⁰ Intussusception by soft melanoma metastases may be intermittent and may not cause obstruction. Multiple polypoid tumors in the jejunum or mid small intestine should suggest a diagnosis of Peutz-Jeghers syndrome or metastases, especially from malignant melanoma. Lipomas are smooth-surfaced, pliable, and often pedunculated lesions that have fat attenuation on CT (Fig. 46-37). The fat of a lipoma should be distinguished from the invaginating mesentery of an intussuscepting polyp. Inflammatory fibroid polyps are typically located in the distal ileum. Pedunculated polyps with long stalks that intussuscept are usually inflammatory fibroid polyps, lipomas, or inverted Meckel's diverticulum (Fig. 46-38).^{81,82} Other causes of intussusception include Henoch-Schönlein purpura, lymphoma, hematomas, and mesenteric lymphadenopathy. Causes of intussusception in patients with AIDS include B-cell lymphoma, Kaposi's sarcoma, mesenteric lymphadenopathy, lymphoid hyperplasia, and intestinal dysmotility.⁸³⁻⁸⁵

Figure 46-38 Inverted Meckel's diverticulum causing intussusception. **A.** Spot radiograph from a small bowel follow-through shows a tapered narrowing of the ileum (large black arrows) at the narrowest point of the intussusceptum. The mucosa of the intussusciens is outlined by refluxed barium (white arrows). **B.** Specimen photograph of the Meckel's diverticulum. There is a long polypoid intraluminal filling defect, which is the invaginated Meckel's diverticulum (M). (From Rubesin SE, Herlinger H, DeGaeta L: *Interlude: Test your skills*. Vascular Disorders of the Small Intestine

SIVA P. RAMAN | KAREN M. HORTON | ELLIOT K. FISHMAN

CHAPTER OUTLINE

Computed Tomography Imaging

Mesenteric Ischemia

Acute Mesenteric Ischemia

Chronic Mesenteric Ischemia

Vasculitis

Large Vessel Vasculitis

Medium Vessel Vasculitis

Small Vessel Vasculitis

Miscellaneous Disorders

Superior Mesenteric Artery Dissection

Trauma

Radiation Enteritis

Splanchnic Artery Aneurysms

Drug-Induced Small Bowel Angioedema

Median Arcuate Ligament Syndrome

Hemangiomas

Summary

Small bowel abnormalities continue to be a significant diagnostic challenge for clinicians and radiologists. Clinicians have historically struggled to diagnose many small bowel diseases because patients typically present with only nonspecific complaints such as abdominal pain, weight loss, or anemia. Therefore, in most cases, the diagnosis of small bowel pathology is highly dependent on the radiologist. Although fluoroscopic barium studies have traditionally been the mainstay in the diagnosis of many small bowel diseases, they have proven to be inherently limited because they image only the lumen of the bowel and provide very little information regarding extraluminal disease. Since its introduction in the late 1970's, computed tomography (CT) has proven to be extremely useful for the evaluation of the small intestine and has been used for the evaluation of such routine conditions as small bowel obstruction and Crohn's disease. However, over the last decade, CT has taken on a larger role in diagnosing a variety of more subtle bowel diseases, including vascular disorders of the small intestine.

Vascular disorders of the small bowel encompass a wide variety of conditions, which primarily affect the mesenteric vasculature. These conditions have traditionally proven very difficult to diagnose radiographically, and ultimately angiography or surgery is relied on to make the correct diagnosis. With the introduction of multidetector CT (MDCT), along with the development of sophisticated three-dimensional imaging tools, it is now possible to image the small bowel

vasculature, as well as the small intestine, in a single examination, offering a thorough evaluation in patients with a wide variety of suspected small bowel vascular disorders.

This chapter will review the current status of imaging regarding a variety of vascular disorders of the small intestine, including mesenteric ischemia and infarction, vasculitis, aneurysms, acute small bowel bleeding, and radiation enteritis. Although a variety of imaging modalities will be discussed, this chapter will concentrate on the use of MDCT and 3D imaging for the diagnosis of these conditions.

Computed Tomography Imaging

The last decade has brought significant improvements in CT technology with the development of 64-, 128-, and 256-slice and, most recently, dual-source scanners. These latest scanners have allowed markedly improved spatial and temporal resolutions, enabled the reliable acquisition of angiographic images at peak arterial enhancement, and reduced motion related artifacts.¹ In addition to improving the image quality of conventional axial images and multiplanar reformats, these technologic advances have improved our ability to create truly isotropic data sets, and have greatly facilitated the creation of 3D reconstructions. These technologic improvements, along with the latest 3D software packages and CT protocol refinements, allow high-resolution images of the small bowel, small bowel mesentery, and mesenteric vasculature to be obtained, largely obviating the need for any other imaging modality.

When a vascular disorder of the small bowel is suspected, the CT examination must be specifically focused to optimize evaluation of the bowel. Prior to the injection of intravenous (IV) contrast, most patients are given a neutral oral contrast agent (e.g., barium sulfate [VoLumen, E-Z-EM, New York]) to distend the small bowel maximally, although in a few select cases (e.g., when acute gastrointestinal hemorrhage is suspected) no oral contrast agent is given. Notably, positive contrast agents are never given because a beam-hardening artifact from the contrast can obscure subtle bowel wall thickening or enhancement abnormalities and can also interfere with 3D postprocessing. An injection of roughly 120 mL of nonionic IV contrast is then administered at a relatively high rate of 3 to 5 mL/s to maximize arterial enhancement. Arterial phase images are acquired at 30 seconds after the injection of contrast, followed by the acquisition of venous phase images at 60 to 70 seconds. The arterial phase images are important in the evaluation of the arterial mesenteric vasculature, small bowel hypoenhancement or hyperemia, vascular malformations, and hypervascular small bowel tumors. The venous phase images are critical for evaluating the mesenteric venous vasculature, identifying subtle areas of bowel wall thickening or hypovascular small bowel tumors,

and complete evaluation of the remainder of the abdomen and pelvis.

Images are acquired with thin collimation, with acquisition of 0.625- to 0.75-mm slices, which are then reconstructed into 3- to 5-mm axial slices for routine interpretation. Coronal and sagittal multiplanar reformations are created directly at most CT scanners immediately after acquisition of the axial source images. Simultaneously, a set of 0.5- to 0.75-mm isotropic² images are used to create 3D reconstructions.

Two primary 3D reconstruction methods, which are typically created interactively by a radiologist at an independent workstation, are the most useful for the evaluation of small bowel vascular disorders:

1. Maximum intensity projection (MIP) imaging involves the acquisition of the highest attenuation voxels in a dataset and the projection of these voxels into a 3D display. These images are most useful for complete visualization of the mesenteric vasculature and for better visualization of abnormalities in the small bowel mesentery by accentuating soft tissue structures and vessels in the midst of mesenteric fat.
2. Volume rendering (VR) is based on a complex algorithm that assigns a specific color and transparency to each voxel in a dataset based on its underlying attenuation and then presenting this data in a 3D display. This technique is the most useful for depicting abnormalities of the bowel wall itself and can accentuate subtle areas of bowel wall thickening or hyperemia.²

Because small bowel loops and the mesenteric vasculature are anatomically complex, and the relationships between different bowel loops and vascular structures are not easy to visualize using any single imaging plane, it is necessary to use a variety of imaging planes during 3D evaluation. To visualize the proximal portion of the celiac axis, superior mesenteric artery (SMA), and inferior mesenteric artery (IMA), the sagittal projection is often the most helpful (Fig. 47-1). However, to visualize the complicated vascular branching of the arterial vessels adequately as they extend distally, coronal or coronal oblique planes are necessary (Fig. 47-2). Similarly, the mesenteric veins are best seen in a coronal projection (Fig. 47-3).

After adequate evaluation of the mesenteric vessels, it is also important to image the bowel (Fig. 47-4) comprehensively. However, visualizing the small bowel in its entirety on the axial images can be difficult and time-consuming, and the full extent and distribution of bowel abnormalities can be difficult to appreciate. Moreover, in our experience, subtle abnormalities in the fold pattern of the small bowel are difficult to appreciate in the axial plane, and the terminal ileum and ileocecal valve tend not to be well visualized. Instead, the small bowel is best visualized in the coronal plane, using cut planes to remove overlapping bowel loops while performing 3D analysis.

Mesenteric Ischemia

ACUTE MESENTERIC ISCHEMIA

Accounting for roughly 5% of all hospital admissions, acute mesenteric ischemia (AMI) is a severe, life-threatening disorder, with mortality rates ranging from 60% to 80%.³⁻⁵ Unfortunately, AMI can be extremely difficult to diagnose clinically. Although patients complain of intense abdominal pain, their physical examination can be misleadingly unremarkable.

Figure 47-1 Normal celiac and superior mesenteric artery anatomy. Sagittal volume-rendered CT angiogram demonstrates normal anatomy of the celiac axis (black arrow) and superior mesenteric artery (white arrow). The left gastric artery (arrowhead) can also be seen arising from the celiac artery.

Laboratory markers are rarely suggestive, although lactate levels can be elevated, and no single laboratory marker is absolutely specific. Ultimately, given the nonspecific presentation of most patients, the diagnosis is contingent on radiology.

A relatively large proportion of cardiac output is routed to the small bowel in the resting state and after a meal, making the small bowel extremely sensitive to decreases in blood flow. Acute mesenteric ischemia can be broadly divided into three major categories: (1) arterial occlusion; (2) venous occlusion; and (3) nonocclusive mesenteric ischemia.

The most common cause is arterial occlusion, which accounts for 60% to 70% of all cases. Arterial occlusion can result from emboli to the SMA, usually in the setting of atrial fibrillation, but also secondary to recent myocardial infarction, mycotic aneurysms, and severe ulcerated plaque in the thoracic or abdominal aorta.⁶ The SMA is considered particularly vulnerable to emboli, given its wide caliber and narrow angle at takeoff, and a large embolus lodged at its origin can occlude blood flow to almost the entire small bowel and right colon. Most emboli lodge in the most proximal aspect of the SMA

Figure 47-2 Coronal volume-rendered CT angiogram. This demonstrates the normal anatomy of the celiac axis (splenic artery, long arrow; common hepatic artery, short arrow) and superior mesenteric artery (arrowhead). The coronal projection allows easy identification of the branches arising from the SMA.

Figure 47-3 Coronal volume-rendered CT image in the venous phase. This demonstrates the normal appearance of the superior mesenteric vein (arrow) and its branches as they join the splenic vein and portal vein at the confluence.

(usually 3 to 10 cm from the origin), although smaller emboli can travel distally and occlude blood flow to a smaller segment of the small bowel or right colon⁷ (Figs. 47-5 to 47-8). Therefore, acute mesenteric ischemia should not be discounted when a relatively short segment of small bowel is involved, rather than the entire SMA territory.

Although most arterial occlusive ischemia of the small bowel is embolic in nature, there are several other causes. Thrombosis of the SMA can occur as a result of severe atherosclerotic disease or in patients with underlying hypercoagulability syndromes. When thrombosis occurs in the setting of underlying

Figure 47-4 Coronal volume-rendered image. This shows the normal appearance of the small bowel.

atherosclerosis, the most common sites of occlusion are at the origins of the SMA and celiac artery. This particular subgroup of patients often has a history of chronic mesenteric ischemia, with development of AMI after superimposed thrombosis of a chronically narrowed and diseased vessel^{5,8} (Fig. 47-9). Notably, although arterial collaterals are not usually found in patients with acute occlusive AMI, patients with a history of chronic mesenteric ischemia and superimposed arterial thrombosis can have evidence of arterial collaterals, a sometimes confusing feature.⁹ More rarely, acute mesenteric ischemia can be seen in the setting of vasculitis, aortic dissection (with extension of an occluding dissection flap into the SMA), occlusion of the SMA by surrounding tumor, or thrombosis of an SMA aneurysm (Fig. 47-10).⁵

Venous occlusion (thrombosis of the superior mesenteric vein [SMV]) accounts for roughly 10% of all cases of AMI. A sizeable percentage of these patients are ultimately found to have a history of a specific hypercoagulability syndrome, personal or family history of unexplained thrombotic episodes, underlying malignancy, or oral contraceptive use, although a discrete cause for the venous occlusion is not found in at least one third of patients (Figs. 47-11 to 47-13).¹⁰ Unfortunately, although the acute symptoms of venous occlusive AMI are usually much less severe compared to those of arterial occlusion, this can lead to considerable delay in presentation and diagnosis, resulting in a mortality rate as high as 40%.⁵

Complicated small bowel obstructions are also a cause of occlusive ischemia because strangulation of the bowel results in occlusion of the vasculature leading to the involved bowel segment. This type of bowel ischemia typically involves a combination of arterial and venous occlusion (Fig. 47-14).

The final major category of acute mesenteric ischemia is nonocclusive ischemia, typically caused by hypotension and diminished blood flow to the small bowel resulting from underlying conditions such as cardiogenic shock, cardiac failure, acute myocardial infarction, severe hypovolemia, trauma, renal failure with overly aggressive dialysis, or severe vasoconstriction from drugs (e.g., digitalis, cocaine). Nonocclusive AMI accounts for roughly 30% of all cases of bowel ischemia and is associated with a 70% mortality rate.¹¹ The odds of acute mesenteric

Figure 47-5 Superior mesenteric artery thrombosis: contrast-enhanced CT images in a patient with acute abdominal pain. **A.** Coronal contrast-enhanced CT image demonstrates dilated small bowel loops in the mid and right abdomen, with pneumatosis identified within several small bowel loops, predominantly in the central abdomen. **B.** Axial contrast-enhanced CT image demonstrates subtle thrombus (arrow) in the superior mesenteric artery. Multiple small bowel loops are dilated with thin walls (no appreciable bowel wall thickening) and a small amount of adjacent ascites, findings that raise concern for bowel ischemia. **C.** Volume-rendered contrast-enhanced image in the sagittal projection demonstrates a large thrombus (arrow) in the superior mesenteric artery, the full extent of which was not appreciated on the axial image. **D.** Volume-rendered contrast-enhanced CT image in the sagittal plane after surgical embolectomy demonstrates a patent superior mesenteric artery.

Figure 47-6 Superior mesenteric artery thrombus in patient with acute abdominal pain. **A.** Coronal contrast-enhanced multiplanar reconstruction demonstrates moderate wall thickening of multiple small bowel loops in the mid abdomen. **B.** Sagittal multiplanar reconstruction demonstrates occlusive thrombus (arrow) in the superior mesenteric artery. There is also calcification and narrowing of the origin of the celiac artery related to chronic atherosclerotic disease.

Figure 47-7 SMA embolism. **A.** Axial contrast-enhanced image demonstrates an acute embolism (arrow) in the SMA. **B.** Coronal contrast-enhanced image demonstrates diffusely hypoenhancing bowel with a relative paucity of bowel wall thickening, a common appearance for acute mesenteric ischemia caused by arterial occlusion.

Figure 47-8 SMA embolism. Axial (A) and coronal (B) contrast-enhanced images demonstrate diffuse hypoenhancement (as a result of acute mesenteric ischemia) of the small bowel in the left hemiabdomen in a patient with subtle SMA embolism.

Figure 47-9 SMA thrombosis. Sagittal volume-rendered CT image demonstrates thrombus (arrow) formation at the origin of the SMA in a region of calcified atherosclerotic plaque.

Figure 47-10 Carcinoid tumor causing mesenteric ischemia. Coronal volume-rendered contrast-enhanced CT image demonstrates a large mesenteric carcinoid tumor (m) encasing the mesenteric vessels, resulting in diffuse small bowel wall thickening related to ischemia.

Figure 47-11 SMV thrombosis. Contrast-enhanced CT image in a patient with acute abdominal pain demonstrates thrombus in the SMV (arrow), with moderate thickening of the small bowel and right colon, which is concerning for bowel ischemia.

Figure 47-12 SMV thrombosis. Coronal volume-rendered contrast-enhanced CT demonstrates moderate thickening of the small bowel (predominantly in the left abdomen), with a large thrombus (arrow) in the SMV.

ischemia in the setting of a low-flow state are increased when the patient has underlying atherosclerotic disease or some other abnormality of the mesenteric vasculature. In younger patients, nonocclusive mesenteric ischemia has been reported with cocaine use, which results in splanchnic vasoconstriction to preserve blood flow to the heart and brain (Fig. 47-15).¹²

Although the diagnosis of AMI was once dependent on angiography, CT has now assumed a primary role in the diagnosis and has proven to be highly effective. Several studies have shown CT to be extremely accurate, with sensitivities greater than 90%.¹³⁻¹⁹ A large meta-analysis studying the accuracy of CT in AMI found a pooled sensitivity of 93.3% and specificity of 95.9%.¹⁸ There is little doubt that CT should be considered the first-line radiologic examination when AMI is suspected.

Computed Tomography Findings

Bowel Dilation. Small bowel dilation is common, although completely nonspecific. In a series of nine patients by Lee and

Figure 47-13 SMV thrombosis. **A.** Axial contrast-enhanced CT demonstrates severe thickening of the small bowel and right colon as a result of venous occlusive ischemia. The intense mucosal enhancement with submucosal hypodensity and edema represents an example of the target or halo appearance. **B.** Axial contrast-enhanced image demonstrates thrombus (arrow) within the SMV, representing the cause of the patient's bowel ischemia.

colleagues, eight of nine patients demonstrated bowel dilation.²⁰ In some cases, dilated bowel can be seen on the basis of an adynamic ileus and interruption of normal bowel peristalsis after an ischemic event and, in other cases, severe bowel dilation can be seen with irreversible transmural bowel infarction.^{21,22} In general, small bowel dilation is more common after venous occlusion than with arterial occlusion.²³

Bowel Wall Thickening. Although not completely specific, bowel wall thickening is the most common CT finding in bowel ischemia, likely on the basis of edema and hemorrhage within the bowel wall. The normal small bowel wall is usually from 3 to 5 mm thick. In the study by Lee and associates,²⁰ bowel wall thickening up to 1.5 cm was noted in patients with mesenteric vein thrombosis. However, it is important to remember that this finding is relatively nonspecific and can be seen in a great variety of other conditions.

Despite being a common finding in AMI, bowel wall thickening is usually seen after venous occlusion or thrombosis and is not a characteristic feature of AMI caused by arterial

Figure 47-14 Closed loop obstruction leading to small bowel strangulation. Coronal contrast-enhanced CT image demonstrates multiple dilated loops of small bowel, many of which appear tethered and radiating toward a central point (arrow) indicating closed loop obstruction. In addition to several markedly thickened, hyperemic loops of small bowel, several loops of bowel in the right abdomen are poorly enhancing. There is also a small amount of interloop ascites. A strangulated ischemic small bowel was found at surgery.

occlusion.²⁴ In patients with AMI on the basis of arterial occlusion, the bowel wall is usually thinned, rather than thickened.^{14,15,20,25} Moreover, although small bowel wall thickening is a common finding in AMI, the presence and degree of bowel wall thickening do not usually correlate with the severity of ischemic damage.²⁵

Bowel Wall Attenuation and Abnormal Enhancement. The appearance of the bowel wall can vary dramatically in cases of bowel ischemia, with a low-density wall usually reflecting submucosal edema; high density within the wall is usually secondary to intramural hemorrhage.^{26,27} Notably, intramural hemorrhage can be a very difficult finding to identify without the aid of noncontrast images because hemorrhage within the bowel wall can be confused with normal enhancement of the wall. Bowel wall edema and hemorrhage are most common after venous thrombosis, although they can also be seen in the setting of reperfusion after arterial occlusion or a nonocclusive AMI.²²

Small bowel ischemia can result in diffuse hypoenhancement of the bowel wall and mucosa, a halo or target appearance, or diffuse hyperenhancement. Diffuse hypoenhancement of the bowel wall is the most specific finding and is usually seen in the setting of acute arterial occlusion or diffuse transmural infarction, regardless of any cause.¹⁵ Diffuse hyperenhancement of the

bowel wall or a halo appearance (with hyperenhancement of the bowel mucosa and diffuse, low-density edema of the submucosal layer) can also be seen with ischemia.²⁶ This mucosal hyperenhancement is usually seen after venous occlusion but can also occur secondary to reperfusion after arterial occlusion or nonocclusive ischemia.

Rarely seen in some patients with ischemia, there can be delayed enhancement of affected loops, likely on the basis of delayed delivery of contrast, as well as contrast persisting in the ischemic segment because of delayed washout.

Stranding and Ascites. Ascites and mesenteric stranding are nonspecific findings in patients with bowel ischemia. Their presence depends on the cause, duration, severity, and site of involvement of the bowel ischemia.²⁵ In general, the presence of mesenteric inflammation and edema is not synonymous with bowel infarction and can be seen with venous occlusion and strangulated bowel obstructions without evidence of frank infarction. Moreover, hemorrhage in the mesentery is a very common finding in cases of venous thrombosis. However, in patients with arterial occlusion, infiltration and edema of the mesentery is a much more ominous finding, often seen in the setting of bowel infarction.²²

Pneumatosis and Portomesenteric Venous Air. Pneumatosis and portomesenteric venous gas are relatively specific signs for transmural bowel infarction, although both are relatively rare (Fig. 47-16). When the mucosal layer of the bowel is disrupted after an infarction, air can extend directly into the bowel wall, producing pneumatosis, seen in 6% to 30% of cases of acute mesenteric ischemia.^{14,15,20,28} This gas can then extend further into the mesenteric veins and portal veins (portomesenteric venous air), a finding that is only seen in 3% to 14% of cases.

The specificity of pneumatosis and portomesenteric venous gas for ischemia and infarction approaches 100%. However, these two findings must be interpreted with a great deal of caution, because, rarely, they can be seen in a few nonischemic conditions as well, including iatrogenic mucosal injury (e.g., after the placement of a gastrostomy tube or jejunostomy tube), infections, bowel trauma, and inflammatory diseases (Fig. 47-17).²⁵ In addition, the radiologist must be careful not to confuse gas tracking along a bowel fold or gas immediately adjacent to the bowel wall with pneumatosis.

Patterns of Ischemia: Arterial Occlusive Ischemia Versus Venous Occlusive Ischemia. Although there can often be a great deal of overlap, the pattern of abnormalities seen on CT secondary to arterial occlusion and venous occlusion can vary. Although bowel wall thickening is commonly thought to represent a critical imaging finding in bowel ischemia, this finding is less commonly seen in cases of arterial occlusion. Rather, the bowel actually tends to become thinned (paper thin bowel) because there is a lack of arterial flow but no appreciable mural edema or intramural hemorrhage. This thinning can also be attributed to loss of intestinal muscular tone after the ischemic event. In most cases of arterial occlusion, hypoenhancement of the small bowel wall and mucosa is present, although hyperemia of the mucosa can rarely be seen in cases of reperfusion after an embolic event. Acutely, the bowel is not usually dilated unless there is evidence of infarction. Finally, there is generally a relative paucity of mesenteric fluid, hemorrhage, and fat stranding,

Figure 47-15 IV drug abuser complaining of pain after recent cocaine use. **A.** Axial contrast-enhanced image through the pelvis demonstrates moderate thickening of the small bowel and right colon. The small bowel demonstrates mucosal hyperemia and low density in the submucosa (halo or target appearance), in keeping with bowel ischemia. **B.** Axial contrast-enhanced CT image through the level of the kidneys demonstrates multiple bilateral renal infarcts. The caliber of the superior mesenteric artery is small (arrow). **C.** Sagittal multiplanar reconstruction demonstrates diffuse narrowing of the superior mesenteric artery, in keeping with IV drug abuse-related vasoconstriction.

Figure 47-16 Bowel infarction with pneumatosis. Contrast-enhanced axial CT image in a patient with mesenteric ischemia and infarcted bowel shows ascites, extensive pneumatosis, and air within the mesenteric veins. Despite emergent surgery, the patient died.

although these three features can be seen when there has been progression to frank bowel infarction. Given these findings, the CT appearance of acute AMI in the setting of arterial occlusion can be relatively difficult to identify; careful attention must be paid to subtle changes in bowel enhancement when an embolus is identified in the SMA.²²

The CT appearance after venous thrombosis is generally much more impressive, as the bowel wall is usually markedly thickened, the wall can be diffusely hypointense because of edema or hyperintense because of intramural hemorrhage, and the mucosa is often avidly hyperemic. The bowel can sometimes be moderately dilated, and there is typically significant mesenteric hemorrhage, edema, fluid, and fat-stranding, even in the absence of true bowel infarction.²²

As one would expect, complicated bowel obstructions demonstrate elements of venous and arterial occlusion, depending on the degree of strangulation, and can have a variable appearance on CT, depending on which vessels are compromised. Nonocclusive mesenteric ischemia does not have a characteristic pattern and can be the most difficult of the three types of AMI to diagnose (Figs. 47-18 and 47-19).

CHRONIC MESENTERIC ISCHEMIA

Chronic mesenteric ischemia (CMI), relatively uncommon (only 5% of all ischemic intestinal diseases) compared with AMI, is most common in older patients with widespread atherosclerotic disease and tends to be most prevalent in women, smokers, and those with diabetes and hypertension.²⁹ Patients usually complain of repeated bouts of abdominal pain, typically occurring immediately after a meal, and often develop fear of food, anorexia, and severe chronic weight loss. Notably, these symptoms do not arise acutely, but develop slowly over many

Figure 47-17 Benign pneumatosis intestinalis.

A, B. Axial noncontrast images demonstrate diffuse pneumatosis in multiple fluid-filled, mildly dilated small bowel loops. The patient was completely asymptomatic, and the pneumatosis was thought to be secondary to recent placement of a jejunostomy tube (arrow in **A**).

Figure 47-18 Nonocclusive mesenteric ischemia.

A, B. Axial contrast-enhanced images in a patient with septic shock demonstrate diffusely thickened, hypoenhancing loops of small bowel. The arterial and venous vasculature (not shown) was widely patent.

Figure 47-19 Nonocclusive mesenteric ischemia.

A, B. Coronal contrast-enhanced images demonstrate diffusely thickened, hypodense bowel in a patient with nonocclusive mesenteric ischemia. The arterial and venous vasculature was widely patent.

years; given the relatively nonspecific nature of the symptoms, the diagnosis is extremely difficult to make clinically.^{5,30}

Atherosclerotic disease of the mesenteric vessels is the primary cause of chronic mesenteric ischemia. However, the presence of atherosclerotic plaque and calcification alone does not automatically suggest that a patient suffers from CMI. Mesenteric atherosclerosis is a relatively common incidental finding and close to 20% of all patients older than 65 years will demonstrate more than 50% narrowing of a mesenteric vessel, without clinical symptoms in all but a few patients. Ultrasound and autopsy studies have confirmed this and have demonstrated that significant atherosclerotic disease can be present in multiple mesenteric arteries without symptoms of ischemia.^{5,31-33} Although rare, nonatherosclerotic diseases can also produce CMI, including such entities as vasculitis, median arcuate ligament syndrome, radiation vasculopathy, and fibromuscular dysplasia.^{5,34}

Most patients will remain asymptomatic unless there is significant disease in at least two of the three major mesenteric arteries (celiac axis, SMA, and IMA; Fig. 47-20). In most cases, atheroma involves the proximal segments of the mesenteric arteries, although more diffuse irregularity and narrowing of a vessel (with associated pruning of smaller branch vessels) can be present in patients with underlying diabetes.³⁰ In patients with more diffuse narrowing, ischemic symptoms can develop, even without a single discrete stenosis reaching the 50% threshold. The ultimate key to the diagnosis of CMI is not the presence of mesenteric vascular narrowing alone, but the simultaneous presence of collateral pathways, because symptoms usually develop when collateral pathways are no longer

sufficient to deliver blood supply to the bowel: Two major collateral pathways are the most common:

1. The pancreaticoduodenal arteries connect the celiac axis and SMA and can flow in either direction, depending on the site of occlusion.³⁰ The presence of large arterial collaterals surrounding the head of the pancreas is often the most important clue to the presence of a hemodynamically significant stenosis of the mesenteric vasculature, and should prompt a close examination of the mesenteric arteries on a sagittal reconstruction (Fig. 47-21).
2. The arc of Riordan and marginal artery of Drummond allow communication between the SMA and IMA (Fig. 47-22). In addition, in severe cases, when the celiac artery, SMA, and IMA are all compromised, pelvic, lumbar, or phrenic collateral vessels can develop.^{5,30,35-38}

Although catheter angiography was once the primary means of establishing the diagnosis of CMI, a number of other cross-sectional imaging modalities are now first-line options when trying to make this diagnosis. Duplex ultrasound has proven to be accurate as a screening test for the proximal mesenteric arteries, based on peak systolic and end-diastolic velocities measured while fasting and in the postprandial state.³⁹⁻⁴¹ The diagnosis of a critical stenosis on ultrasound is based primarily on velocity criteria, with a velocity of more than 275 cm/s in the proximal SMA or more than 200 cm/s in the proximal celiac artery in a fasting patient suggestive of a 70% or greater stenosis.⁴² Magnetic resonance angiography (MRA) has also been shown to correlate accurately with conventional angiography and can be a valuable option in patients for whom iodinated contrast agents are contraindicated.^{43,44} Recent MR imaging (MRI)

Figure 47-20 Chronic mesenteric ischemia.

Figure 47-21 CT angiogram in a patient with celiac artery stenosis. **A.** Sagittal volume-rendered CT image shows marked narrowing (arrow) at the origin of the celiac artery. **B.** Coronal MIP image shows the pancreaticoduodenal collateral pathways (arrow) that have developed between the SMA and celiac axis.

Figure 47-22 Marginal artery of Drummond. This coronal volume-rendered image demonstrate several large collateral vessels, including a large marginal artery of Drummond (arrowheads), in a patient with superior mesenteric artery stenosis. This is an important collateral pathway between the IMA and SMA.

protocols have also incorporated imaging of patients before and after a meal. Regardless, CT is the primary modality whereby the diagnosis of CMI is made. CT offers optimal visualization of the involved vascular segments, the ability to rotate and view the involved segments from any perspective using 3D techniques, and the ability to view calcification and soft plaque rather than the vessel lumen alone and, perhaps most importantly, it provides the added advantage of evaluating the bowel and nonvascular portions of the abdomen and pelvis.

Vasculitis

A general term encompassing a wide variety of diseases that result in inflammation and necrosis of blood vessels, vasculitis is often classified based on the size of the affected vasculature. Three primary categories of vasculitis have been described: (1) large vessel vasculitis affects the aorta and its major branches (the two most common types are Takayasu's arteritis and giant cell arteritis); (2) medium vessel vasculitis affects the visceral arteries and their branches, with classic examples in this category including polyarteritis nodosa, Kawasaki disease, and primary granulomatous central nervous system vasculitis; and (3) small vessel vasculitis affects arterioles, venules, and capillaries. This category includes the largest number of discrete entities; the most common are lupus vasculitis, Henoch-Schönlein purpura, Wegener's granulomatosis, and Churg-Strauss syndrome.^{45,46} Furthermore, some forms of vasculitis (usually small vessel vasculitis) have been termed *secondary vasculitis*

when caused by an underlying collagen vascular disease (e.g., lupus vasculitis, Behçet's disease), infection, malignancy, or drug reaction.⁴⁶

Each of these entities affects a characteristic distribution of blood vessels. The involvement of the small bowel can vary greatly, depending on the type of vasculitis and the vessels involved.

LARGE VESSEL VASCULITIS

Of the large vessel vasculitides, Takayasu's arteritis is the most likely to involve the mesenteric vessels. Takayasu's arteritis is a chronic granulomatous inflammatory disease of the large arteries, usually affecting the aorta and its main branches.⁴⁵ Women are affected about 10 times more often than men, and there appears to be a unique predilection for Asian patients. Takayasu's arteritis classically involves the aortic arch, but can also affect the abdominal aorta and mesenteric branches, resulting in abdominal pain, ischemia (acute or chronic), hemorrhage, or strictures.⁴⁵

The radiographic diagnosis of mesenteric involvement by Takayasu's arteritis was once typically made using conventional angiography. However, these findings can now be well depicted with MDCT of the mesenteric vessels, with 3D reconstructions

depicting the full extent of the patient's disease. Particularly in the acute phase, the walls of the superior mesenteric artery can appear thickened, usually more regular and extensive than in atherosclerotic disease, and typically encompassing a much longer segment. As the involvement becomes more chronic, long-segment strictures and stenoses of the SMA can develop, along with poststenotic dilation, aneurysms and, in severe cases, occlusion, with collateral vessel formation. Unlike conventional angiography, CT also has the advantage of being able to visualize changes in the small bowel as a result of compromised blood flow, including increased or decreased wall enhancement, wall thickening, mesenteric stranding, and ascites and, in cases of frank infarction, pneumatosis and mesenteric venous gas.

MEDIUM VESSEL VASCULITIS

Of the medium vessel vasculitides, polyarteritis nodosa (PAN) is the most likely to affect the mesenteric arteries (Fig. 47-23). PAN is a fibrinoid necrotizing vasculitis that weakens the arterial wall of small and medium-sized vessels, leading to the formation of aneurysms, typically at branch points. The kidneys and renal arteries are the most commonly involved, with abnormalities present in up to 80% to 90% of patients. However, the small intestine and mesenteric vessels are also involved in over

Figure 47-23 Polyarteritis nodosa. A. Contrast-enhanced CT demonstrates thickening of the superior mesenteric artery (arrow). **B.** Sagittal reconstruction demonstrates mural thickening (arrow) of the proximal portion of the superior mesenteric artery, reflecting vasculitic involvement of the SMA.

50% of cases, with the small bowel being the most commonly involved portion of the gastrointestinal (GI) tract. Bowel involvement by PAN is thought to portend a particularly poor prognosis.⁴⁷ Abdominal pain is reported in up to two thirds of patients with this disorder, usually from ischemia, and GI hemorrhage and bowel perforation are common complications.^{45,46,48} In a series of 24 patients with polyarteritis nodosa and GI tract involvement, 54% developed a surgical abdomen, of whom 3 subsequently died.⁴⁵

Radiologic diagnosis is best made with high-quality CT angiographic images, which demonstrate aneurysms involving the renal, mesenteric, hepatic, splenic, or peripancreatic arteries.⁴⁹ Although this pattern of aneurysm formation is highly suggestive of PAN, patients with necrotizing angitis secondary to IV drug use, lupus vasculitis, and Wegener's granulomatosis can also have a similar distribution and appearance.

SMALL VESSEL VASCULITIS

Of the small vessel vasculitides, those most likely to involve the small bowel include Henoch-Schönlein purpura, systemic lupus erythematosus (SLE), and Behçet's disease.

Henoch-Schönlein Purpura

A small vessel vasculitis of unknown cause, Henoch-Schönlein purpura is the most common vasculitis of childhood.^{50,51} Although generally thought of as a purely pediatric condition, up to 30% of patients may be older than 20 years.⁴⁵ The disorder is characterized by the deposition of IgA-predominant complexes in the skin, joints, kidneys, and GI tract. The skin disease is typically the first manifestation, appearing as a petechial rash with purpura, often on the lower extremities.⁵¹

GI tract involvement can occur in up to 60% of patients, most often resulting in abdominal pain related to ischemia.⁵² Occult or overt GI bleeding is a very common feature, seen in up to 52% of patients, and intramural hematoma within the bowel wall is not uncommon.⁵⁰ Any part of the GI tract can be involved, but the small bowel is the most frequently involved site. Although certainly not specific for the disease, common CT findings include bowel wall thickening, bowel wall dilation, luminal narrowing, fold thickening, and ulceration (Fig. 47-24).⁵³ Multiple different bowel loops can be involved, and areas of intervening normal bowel can be seen. There are typically multiple stigmata of intense abdominal

inflammation, including enlarged mesenteric lymph nodes, engorged mesenteric vasculature, ascites, and mesenteric stranding.⁵² Particularly when presenting in the pediatric population, intussusception is a common surgical complication, occurring in up to 13.6% of patients, with the most common sites being ileoileal and ileocolic.⁵⁰ It is thought that this unique predisposition toward intussusception, particularly in locations within the small bowel, which are uncommon in normal children, is related to hemorrhage and edema within the bowel wall serving as a pathologic lead point.⁵⁰ Although the CT appearance of the bowel can be dramatic, less than 5% develop true bowel infarction or perforation, and the vast majority of cases will resolve without sequelae.⁴⁵

Systemic Lupus Erythematosus

SLE is a complex autoimmune disease with multisystem involvement that can affect any portion of the GI tract as a result of immune complex deposition in the wall of small arterioles feeding the bowel.^{45,54,55} Moreover, patients with SLE are further at risk for bowel complications, given that 27% to 42% of SLE patients are hypercoagulable because of underlying antiphospholipid syndrome, placing them at high risk for the development of mesenteric arterial or venous thrombosis.^{56,57} These two features (arteriolar vasculitis and central mesenteric thrombosis) place these patients at unique risk of bowel ischemia.

Abnormal CT findings in the bowel are usually reflective of bowel ischemia (see Fig. 47-20), including bowel wall thickening, edema, intramural hemorrhage, altered mucosal enhancement or, in more advanced cases, pneumatosis or mesenteric venous gas (Fig. 47-25).⁵⁴ 3D and multiplanar imaging of the mesenteric vessels are critical to avoid missing subtle cases of arterial or venous thrombosis. Particularly in those patients in whom the amount of thrombus is small and involves only a short segment, the abnormality can be easy to miss on conventional axial images. In patients in whom the bowel ischemia is secondary to the vasculitis itself (rather than thrombosis), subtle beading or pruning of the mesenteric artery branches may be most apparent on 3D MIP images.

Behçet's Disease

A small vessel vasculitis usually affecting young males (age 11 to 30 years), Behçet's disease is classically characterized by oral and genital ulcers, ocular inflammation, arthritis, and skin

Figure 47-24 Henoch-Schönlein purpura.

A, B. Contrast-enhanced CT image demonstrates moderate small bowel thickening. The small bowel is thickened with mucosal hyperemia and has a target appearance. This was ultimately proven to be a case of bowel ischemia secondary to Henoch-Schönlein purpura.

Figure 47-25 Lupus vasculitis in a 32-year old woman with lupus, abdominal pain, and elevated lactic acid level. This coronal contrast-enhanced image shows moderate ascites, marked thickening of the small bowel in the mid abdomen and left upper quadrant, and mucosal hyperemia and low density in the submucosal layer of the bowel wall. These findings reflect bowel ischemia secondary to lupus vasculitis.

lesions.⁴⁶ It is an uncommon necrotizing vasculitis of unknown cause that may involve multiple organs, including the GI tract in up to 50% of cases. The two most common locations in the GI tract are the distal ileum (including the ileocecal region) and esophagus, with involvement of the bowel characterized by severe ulceration. Typically, the diagnosis is made through biopsy of the mucosal ulcers, and patients are subsequently treated with steroids.

Given that the most common site of involvement in the small bowel is the distal ileum, Behçet's involvement in this location can very much mimic Crohn's disease. Severe ulcerations in the bowel wall place the patient at high risk of developing fistulas, sinus tracts, abscesses, and other complications, all of which can misleadingly suggest Crohn's disease (particularly given the patient population). Bowel wall thickening on CT can be severe and even masslike in appearance, asymmetrically involving the bowel wall, and can be confused with malignancy, particularly lymphoma (Fig. 47-26). The presence of large asymmetric ulcerations is a feature most often appreciated on fluoroscopic studies, and barium studies also demonstrate marked fold thickening of the involved bowel, often appearing focal and masslike and sometimes mimicking a small bowel lymphoma or neoplasm. In a series of 28 patients by Ha and co-workers with intestinal Behçet's, it was suggested that discrete, masslike, polypoid lesions in the bowel were more common in patients without complications, whereas bowel wall thickening was more common in patients with complications.⁵⁸ Similarly, most patients without complications had very little inflammatory change or fluid adjacent to the involved bowel segments, whereas severe mesenteric infiltration was more

Figure 47-26 Behçet's disease. Coronal contrast-enhanced CT demonstrates marked thickening of the distal ileum (arrow), somewhat masslike in appearance. This was originally thought that it might represent lymphoma, but was found to be manifestation of Behçet's disease.

common in patients with complications such as peritonitis or perforation.

Acute Small Bowel Bleeding

Although much less common than the colon, the small bowel is an important site of GI bleeding, perhaps accounting for 3% to 5% of all cases.⁵⁹ The most frequent causes of small bowel bleeding include ulcerations, tumors, Crohn's disease, angiodysplasia, and vascular malformations.⁶⁰ Usually suspected after negative upper and lower endoscopy, small bowel bleeding is notoriously difficult to diagnose. Although some endoscopic procedures have been developed to evaluate the small bowel, these have not proven especially efficacious in identifying sources of bleeding. For example, push enteroscopy involves the use of a long endoscope to visualize the small bowel beyond the reach of a conventional endoscope. However, this technique is naturally limited by its ability to reach only 80 to 120 cm beyond the ligament of Treitz (thus not evaluating the distal small bowel), is time-consuming, and can miss small bowel bleeding that is intermittent in nature.^{59,61} Capsule endoscopy, which involves the evaluation of the small bowel with a wireless video capsule, has become an option for evaluating the entire small bowel. However, this technique is expensive, time-consuming, can be problematic in patients with bowel strictures and narrowing, and can also miss those with intermittent bleeding. Moreover, this technique is limited to the evaluation of the mucosal layer of the bowel and will miss bleeding from submucosal lesions.⁵⁹ Most importantly, given its time-consuming nature, capsule endoscopy is best reserved for cases of chronic bleeding rather than for the acute setting.

Although the two most common radiologic studies used in the setting of GI bleeding have traditionally been technetium 99m-labeled red blood cell (RBC) scans and catheter angiography, both these modalities have significant limitations in the

small bowel. Although tagged RBC scans can detect low rates of bleeding (>0.2 mL/min), are noninvasive, and can detect intermittent bleeding over long periods of time, this modality is limited by its poor spatial resolution and inability to localize sites of bleeding accurately. Catheter angiography is limited by its ability to only detect relatively rapid rates of bleeding (at least 1 mL/min) and by its difficulty in detecting intermittent hemorrhage. Moreover, it is an invasive modality with associated risks to patient safety and also suffers from poor contrast resolution, which can limit its ability to characterize the true site of bleeding accurately.⁶²

Computed Tomography in the Diagnosis of Gastrointestinal Bleeding. Computed tomography has taken on a growing role in the evaluation of small bowel bleeding in the acute setting, with its ability to identify extraluminal sources of bleeding (e.g., submucosal tumors, vascular malformations) and precisely localize the anatomic site of bleeding. Although the data regarding the use of CT in the acute setting is still relatively sparse, studies performed in animal models suggest that bleeding may be detectable at 0.35 mL/min, better than catheter angiography, and only slightly above the rate detected by tagged RBC studies. In the acute setting, the sensitivity of CT for acute GI hemorrhage has reported to be as high as 92%.^{59,63} Moreover, CT may be a better option than capsule endoscopy, even in the subacute or chronic setting. In a study by Huprich and colleagues, CT enterography (with arterial and venous phase imaging and the use of a neutral oral contrast agent to distend the small bowel) was more sensitive for the source of small bowel bleeding than capsule endoscopy (88% vs. 38%); CT's primary advantage was in cases of bleeding caused by small bowel masses.⁶⁴

Technique. Like other modalities, CT is somewhat limited when bleeding is intermittent, and it is critical that the study be performed when the patient is actively bleeding. In the acute setting, no oral contrast should be administered; positive oral contrast agents can mask sites of active bleeding, whereas neutral contrast agents (e.g., water, VoLumen) can potentially dilute sites of bleeding.^{62,65} Moreover, the potential need for intervention in the acute setting makes any oral ingestion contraindicated. However, neutral contrast agents may be of use in the chronic setting because there is less focus on identifying active bleeding and more focus on identifying an occult small bowel mass, ulcer, or vascular malformation.

Brisk injections (4 to 6 mL/s) of IV contrast are generally necessary because acquiring images at peak arterial enhancement improves the chances of visualizing active contrast extravasation or subtle vascular malformations. Portal venous phase images are also an important part of a GI bleeding protocol because they facilitate the visualization of hypovascular small bowel tumors and subtle bowel wall thickening. Some institutions use a noncontrast phase prior to the administration of contrast to avoid mistaking radiodense ingested materials, medications, sutures, or surgical clips for sites of bleeding. However, we do not routinely acquire noncontrast images at our institution because any active site of bleeding should change in configuration over the arterial and venous phases and ingested foreign material should remain identical in appearance.

Findings. In the acute setting, extravasated contrast material within the bowel is the most critical sign of active bleeding. This extravasation can be quite subtle in the most difficult cases,

although in the most obvious situations, an entire small bowel loop can be filled with extravasated contrast (Figs. 47-27 and 47-28). Importantly, normal mucosal enhancement when the bowel is not particularly well distended can be mistaken for active extravasation, as can hyperdense older clotted blood. In both these situations, it is important to note that active extravasation will typically have much higher Hounsfield attenuations (usually >90 HU) compared with older clotted blood or mucosal enhancement (usually <90 HU).⁶⁵ This is discussed more fully in Chapter 125.

Miscellaneous Disorders

SUPERIOR MESENTERIC ARTERY DISSECTION

Most cases of SMA dissection reflect extension of an aortic dissection into the SMA (Fig. 47-29). The dissection flap can extend a variable length into the SMA and, in some cases, can result in complete occlusion of the vessel, with resulting bowel ischemia. However, isolated visceral artery dissection (without an associated aortic dissection) is a rare phenomenon, usually involving the SMA, with the celiac and common hepatic arteries involved less often (Figs. 47-30 and 47-31). When this occurs, it is thought that the most likely causes are an intrinsic abnormality of the vessel wall, such as underlying vasculitis, cystic medial necrosis, fibromuscular dysplasia (FMD), aneurysm, or collagen vascular disease.⁶⁶⁻⁶⁹

Although rare, the identification of visceral artery dissections is becoming more common with improved CT scanner technology, multiplanar reformats, and 3D reconstructions. In particular, the orientation of the dissection flap, which can have a helical configuration, as well as a volume-averaging artifact, can make it difficult to identify an SMA dissection on axial images, and evaluation of the artery in multiple planes is mandatory. The dissection flap should thereby be easily visualized

Figure 47-27 Acute gastrointestinal bleeding on CT. Contrast-enhanced arterial phase CT image demonstrates active extravasation within the duodenum (arrow), which is distended with hematoma. This was found to represent a bleeding duodenal ulcer when further evaluated with endoscopy.

Figure 47-28 Acute small bowel hemorrhage on CT. Contrast-enhanced arterial (A) and venous (B) phase images demonstrate active extravasation of contrast material (arrow) into the right lower quadrant small bowel. The extravasated contrast changes in configuration and enlarges over the two phases, allowing it to be differentiated from ingested hyperdense material, even without noncontrast images.

Figure 47-29 Dissection involving the superior mesenteric artery. Axial contrast-enhanced CT (A) and coronal volume-rendered (B) images demonstrate a dissection (arrows) involving the superior mesenteric artery

on CTA, and is typically located a few centimeters distal to the SMA origin, sometimes resulting in narrowing or occlusion of the lumen.⁷⁰ Patients can present with clinical symptoms related to intestinal ischemia or hemorrhage, and the decision to undergo operative repair, endovascular intervention, or conservative therapy is largely contingent on patient symptoms and the presence of bowel ischemia.⁶⁹

TRAUMA

Bowel and mesenteric injury is found in 5% of patients undergoing laparotomy after significant blunt abdominal trauma.⁷⁰ The mesenteric side of the small intestine is more vulnerable to vascular tears, resulting in mesenteric blood or hematoma. The antimesenteric border of the bowel, on the other hand, is more likely to perforate.⁷¹ The radiologist must have a high index of suspicion for mesenteric injury or bowel injury in trauma patients with fluid or increased density in the mesentery, whether or not pneumoperitoneum is present.

Another finding that can be seen in the setting of trauma and hypovolemic shock is the so-called shock bowel complex, in which there is severe submucosal edema and intense mucosal enhancement of the small bowel (Fig. 47-32). This appearance, which is often associated with other evidence of hypovolemic shock (including a flattened inferior vena cava [IVC], narrow aorta, peripancreatic fluid, diminished enhancement of the spleen and liver, and intense enhancement of the adrenal glands) should not be confused with bowel ischemia or bowel injury, because the abnormal appearance of the bowel should resolve with supportive therapy and volume resuscitation.⁷²

RADIATION ENTERITIS

The small intestine is the most common site of injury in patients undergoing radiation therapy, particularly in patients receiving high doses of radiation over a relatively short period of time. Patients with a history of previous intra-abdominal surgery or peritonitis are particularly susceptible to radiation enteritis

Figure 47-30 Dissection of the superior mesenteric artery. Contrast-enhanced axial CT image (A) and coronal volume-rendered reconstruction (B) demonstrate a dissection flap (arrows) in the superior mesenteric artery.

Figure 47-31 Sagittal contrast-enhanced CT. This demonstrates mild aneurysmal dilation of the celiac artery, with a dissection flap. No dissection was identified within the aorta itself.

because of the immobility of the intestine as a result of adhesions. Patients with diabetes or atherosclerotic disease are also at additional risk because the radiation is more likely to result in endarteritis and, ultimately, fibrosis. Patients can present with acute symptoms of radiation enteritis (pain, diarrhea, bleeding) during the radiation therapy, or symptoms of chronic radiation injury (pain, obstruction, malabsorption) can occur at any time point after the therapy (including decades later).

The diagnosis of radiation enteritis is usually made clinically based on the patient's history and presentation. However, CT can be helpful to confirm the suspected diagnosis and determine the severity and extent of involvement. In patients with acute radiation enteritis, CT will typically demonstrate thickening and edema of the small bowel wall, often with mucosal hyperemia, with associated mucosal ulceration generally best

Figure 47-32 Shock bowel in a 23-year-old woman immediately after a motor vehicle accident. Contrast-enhanced CT demonstrates pneumoperitoneum, a flattened IVC (arrow) suggestive of hypovolemia, and a diffusely thickened, avidly enhancing small bowel. This constellation of findings represents the shock bowel complex.

appreciated on fluoroscopic barium studies (Fig. 47-33). Intramural hemorrhage can often be present in the acute stage. Over time, patients with chronic radiation injury can demonstrate stenoses, adhesions, strictures, small bowel obstruction, and fistulas. In the most obvious cases of chronic radiation injury, the small bowel mucosa will appear completely effaced, resulting in a smooth featureless appearance of the small bowel on

CT and fluoroscopic studies, often referred to as ribbon or toothpaste bowel.

SPLANCHNIC ARTERY ANEURYSMS

Splanchnic artery aneurysms are rare, with an incidence of 0.01% to 0.25% in autopsy series.⁷³ Most patients with splanchnic artery aneurysms are asymptomatic, and the diagnosis is most often made incidentally.⁷⁴ However, in some cases, these aneurysms can rupture, and patients can then present with abdominal pain and mesenteric hemorrhage.

Figure 47-33 Radiation enteritis. Axial contrast-enhanced CT image in a patient after radiation therapy for lymphoma demonstrates moderate thickening of several small bowel loops in the right abdomen, thought to be secondary to radiation enteritis. There is also minimal mesenteric stranding and ascites.

The splenic artery is the most commonly involved (60%), followed by the hepatic artery (20%), SMA (5.5%), celiac artery (4%), pancreatic arteries (2%), and gastroduodenal artery (1.5%).⁷⁵ The diagnosis can be made using any modality, including CT, MRI, ultrasound (US), or angiography, although MDCT is the easiest procedure for making the diagnosis, and 3D reconstructions can nicely illustrate the 3D shape and morphology of the aneurysm, providing a roadmap for surgical or endovascular repair. Although the treatment of these aneurysms has traditionally been surgical, endovascular repair has become increasingly common.⁷⁵

The most common location for an SMA aneurysm is within the first 5 cm of the vessel; the most common causes for an aneurysm in this location include endocarditis, atherosclerosis, and pancreatitis. Complications can include thrombosis and rupture, each of which carries a high mortality rate, because complications involving SMA aneurysms place the patient at great danger of small bowel ischemia. Celiac artery aneurysms are more frequent in men than women, and 75% of patients present with clinical symptoms, typically pain (Figs. 47-34 and 47-35).⁷⁶ The risk of rupture is 13%, with an almost 100% mortality rate when rupture occurs.⁷⁷ The most common cause of a celiac artery aneurysm is atherosclerotic disease, and most aneurysms occur either at or near the origin of the vessel.

DRUG-INDUCED SMALL BOWEL ANGIOEDEMA

A self-limited process characterized by the vascular leakage of serum from small vessels, angioedema is likely related to the abnormal release of bradykinin, resulting in severe vasodilation. Although in rare cases hereditary caused by a C1q esterase deficiency, angioedema is usually drug-related. Angiotensin-converting enzyme (ACE) inhibitors are the drugs most commonly known to cause angioedema, and most clinicians are familiar with the swelling, flushing, and facial edema that can characterize this drug reaction. Other drugs, however, including IV contrast itself, can also produce angioedema.^{78,79}

Figure 47-34 Celiac artery aneurysm. **A.** Axial contrast-enhanced CT image in the arterial phase demonstrates an aneurysm (arrow) of the celiac artery. **B.** Volume-rendered (VR) projection nicely demonstrates the complex shape of the celiac artery aneurysm, which begins approximately 1.5 cm distal to the origin of the celiac artery.

Figure 47-35 Celiac artery aneurysm. Axial (A) and sagittal (B) contrast-enhanced CT images demonstrate aneurysmal dilation of the celiac axis (arrows).

Although classically associated with the oral and respiratory mucosa, angioedema can also be seen in the small bowel, and has been increasingly reported in association with ACE inhibitor usage. The appearance on CT can be very striking, with marked segmental thickening of small bowel loops and intense mucosal enhancement, often resulting in a mistaken diagnosis of bowel ischemia or vasculitis.⁷⁸ Notably, however, this bowel abnormality should be relatively short-lived and transient if the offending drug is discontinued.

MEDIAN ARCUATE LIGAMENT SYNDROME

The median arcuate ligament is a fibrous arch that unites the right and left crura on either side of the aortic hiatus. Although there is a great deal of variation in the shape and orientation of the median arcuate ligament, in most individuals the ligament crosses above the celiac origin and anterior to the aorta. However, in 10% to 24% of individuals, the median arcuate ligament has a low insertion across the origin of the celiac axis, an anatomic abnormality that can be exacerbated in patients with an abnormally high takeoff of the celiac artery.^{80,81} This abnormal positioning of the median arcuate ligament can result in varying degrees of celiac artery compression.

In rare cases, the compression can be hemodynamically significant, resulting in collateral flow to the celiac artery from the SMA (Figs. 47-36 and 47-37). A small subset of individuals with this low insertion will be symptomatic, presenting with symptoms similar to those of CMI. In particular, most patients with clinical symptoms tend to be young women, and there is a tendency to develop symptoms after meals or exercise, or with inspiration. The cause of pain in patients with median arcuate ligament syndrome is controversial; some believe that the pain is a result of compromised blood flow and shunting of blood away from the SMA, but others think that the pain is a result of compression or chronic irritation of the celiac plexus.^{30,81-84} Because of controversy about the true cause of pain, there is a

great deal of disagreement about the best management strategy. There have been arguments in favor of open surgical release of the median arcuate ligament and endovascular angioplasty with stenting.

Although the diagnosis was once typically made with catheter angiography, CT with 3D reconstructions is now clearly the best means of evaluation. Sagittal reconstructions are of the utmost importance because the abnormally low insertion of the median arcuate ligament, compression of the celiac artery, and a characteristic-shaped indentation on the proximal celiac artery can all be optimally illustrated (see Figs. 47-31 and 47-32). Moreover, when the compression is hemodynamically significant, poststenotic dilation of the celiac artery can be seen, and prominent collaterals surrounding the pancreatic head from the SMA through the gastroduodenal and peripancreatic arteries can be present.⁸⁵ Also, given that median arcuate ligament compression is almost certainly a dynamic process, inspiratory and expiratory scans can be performed to evaluate for worsening compression on inspiration (Fig. 47-38).

HEMANGIOMAS

GI hemangiomas are rare benign vascular tumors that can occur anywhere in the GI tract, but are most frequently located in the small intestine (usually the jejunum).⁸⁶ Hemangiomas account for 7% to 10% of all benign small bowel tumors.⁸⁷ Histologically, hemangiomas are classified according to their major component. Capillary hemangiomas are composed of small capillaries with thin walls and blood-filled spaces lined by endothelial cells. Cavernous hemangiomas consist of larger blood-filled sinuses lined by single or multiple layers of endothelial cells.⁸⁸

Small bowel hemangiomas can be single or multiple and can be associated with hemangiomas or vascular malformations in other organs, such as the liver and skin. Accordingly, there have been reported associations between GI hemangiomas and

Figure 47-36 Median arcuate ligament syndrome. **A.** Sagittal contrast-enhanced image demonstrates a hooklike or J-shaped appearance of the proximal celiac axis, which is narrowed (arrow). **B.** Coronal MIP image shows enlarged and dilated pancreaticoduodenal collaterals supplying the celiac from the SMA.

Figure 47-37 Median arcuate ligament syndrome. **A.** Sagittal contrast-enhanced image shows severe narrowing of the proximal celiac artery by a prominent median arcuate ligament. **B.** Coronal CTA with MIP shows enlarged and dilated pancreaticoduodenal collaterals supplying the celiac from the SMA.

Figure 47-38 Median arcuate ligament syndrome. Expiratory (A) and inspiratory (B) contrast-enhanced sagittal CT images in a patient with median arcuate ligament syndrome. A. The expiratory image demonstrates a characteristic J-shaped indentation on the proximal celiac artery, with resultant compression. B. The degree of celiac artery compression increases on the inspiratory image.

Osler-Weber-Rendu syndrome, Maffucci's syndrome, Klippel-Trenaunay-Weber syndrome, and congenital blue rubber bleb nevus syndrome.⁸⁸

With hemangiomas, 90% eventually present with clinical symptoms, usually acute or chronic GI hemorrhage. Moreover, particularly when large, these lesions can result in small bowel obstruction, intussusception, or perforation. Nevertheless, small bowel hemangiomas have proven extremely difficult to diagnose radiographically, particularly prior to the CT era. In a review of the Japanese literature by Akamatsu and associates, a preoperative diagnosis was possible in only 24% of patients using small bowel series, angiography, or scintigraphy.^{88a} Although some of these lesions are undoubtedly now being diagnosed with capsule endoscopy, CT has emerged as a very good option for diagnosing these masses. Although there have been few reports in the literature, the appearance can vary greatly. In some cases, mural thickening of the involved bowel segment is seen, with intense associated enhancement on arterial phase images, whereas in other cases, a distinct hypervascular mass or a tangle of abnormal serpiginous vessels may be identified (Fig. 47-39). The presence of phleboliths within the lesions is readily apparent on CT and can strongly suggest the diagnosis.⁸⁸⁻⁹⁰

Summary

Advances in CT technology—the refinement of CT protocols to study the small bowel and mesenteric vasculature specifically and the development of modern 3D reconstruction software—over the last few years have markedly improved our ability to diagnose diseases of the small bowel. Whereas CT was once

Figure 47-39 Contrast-enhanced axial CT image. This demonstrates a 9-mm enhancing lesion in the distal small bowel (arrow) ultimately proven to represent a hemangioma.

limited to only the most basic diagnoses in the small bowel, and fluoroscopic studies were used to make more subtle determinations and diagnoses, CT should now be considered as the first-line imaging study in patients with suspected vascular disorders of the small bowel. CT can accurately image the small bowel and mesenteric vasculature with a high degree of detail and subtlety and can identify a wide range of pathologies.

Continent Ileostomy Reservoir

Ileoanal Pouches

Small Bowel Transplantation

Surgical treatment of disease of the small bowel requires the use of relatively few operative techniques, and most of these surgical interventions are applicable to any segment of the jejunum and ileum. Primarily, they include enterotomy for removal of polyps or foreign bodies, enteroplasty for treatment of strictures, enterectomy for resection of obstructed, traumatized, neoplastic, or necrotic segments, plication to prevent intestinal obstruction, and creation of ostomies or mucous fistulas for feeding or drainage purposes.¹ In addition, the small bowel is used for the surgical construction of reservoirs after gastrectomy and proctocolectomy and for the reconstitution of biliary and pancreatic flow into the gastrointestinal (GI) tract. Another development is the surgical option of small bowel transplantation for the treatment of select patients with short bowel syndrome and intestinal failure.

Radiologic studies are seldom performed as routine follow-up of the surgical procedure, but are done to assess the integrity of the small bowel or investigate postoperative complications. Appreciation of postoperative anatomy and associated intestinal alterations can be especially important because the pertinent surgical history may be incomplete or even unknown at the time of diagnostic imaging. In patients with a history of small bowel surgery who present with GI symptoms, the postoperative anatomy and site of any anastomosis can be evaluated by small bowel enteroclysis techniques.^{2,3} However, experience with CT enteroclysis is limited to a few institutions. An alternative technique for achieving adequate bowel distention is CT enterography, which does not require intubation but the patient must drink large quantities of oral contrast in a short period of time. Considering many factors specific to the patient and institution, the radiologist would make a choice between the intubation-infusion method (enteroclysis) and the oral approach (enterography).

Small Bowel After Gastric Surgery

Important although uncommon alterations in small intestinal physiology or anatomy may occur after certain operations on the stomach. In the postgastrectomy syndrome, various pathophysiologic disorders result from interruption of the pyloric sphincter mechanism or from the sequelae of a vagotomy. Rapid influx of hyperosmotic gastric contents into the small bowel may manifest clinically as the dumping syndrome, with symptoms of postprandial cramping and urgent diarrhea. Mild luminal dilation and hypermotility of the efferent jejunum can be observed on small bowel studies. Serotonin, enteroglucagon, and vasoactive intestinal polypeptide are also released systemically by the small intestine in response to luminal distention and are partly responsible for the vasomotor component of dumping.⁴ Small bowel dysmotility with bacterial colonization, intestinal malabsorption, and impaired pancreatic and biliary function may also contribute to postvagotomy diarrhea.⁵

AFFERENT LOOP OBSTRUCTION

An afferent loop may be created with an esophagoenterostomy, gastroenterostomy, or enteroenterostomy that results from various gastric or pancreaticogastric operations. In Billroth II gastroduodenostomy, the afferent loop is the duodenum, in Whipple's procedure it is the Roux jejunal limb, and in Roux-en-Y gastric bypass the afferent loop is the duodenum and proximal jejunum. Afferent loop obstruction, also referred to as biliopancreatic limb obstruction, is an uncommon complication of these surgical procedures and occurs with variable clinical severity, acuteness, and chronicity.⁶ Afferent loop syndrome refers to chronic partial obstruction of an afferent loop. Causes include stenosis of the anastomosis, adhesions, retrograde intussusception, volvulus, internal hernia, recurrent neoplasm, and inflammatory disease.^{6,7} The clinical diagnosis of afferent loop obstruction can be difficult because patients may have vague symptoms or the classic finding of bilious vomiting with relief of abdominal pain. Acute obstruction can result in pancreatitis, whereas chronic progression of the syndrome can result in malabsorption, intestinal bleeding, or perforation.⁸

Abdominal radiographs are often normal because the obstructed afferent loop is fluid-filled because of ongoing accumulation of biliary, pancreatic, and intestinal secretions. GI barium studies may suggest the diagnosis if there is nonfilling of the afferent loop or preferential filling of a dilated afferent loop associated with stasis (Fig. 48-1). However, the efficacy of barium studies is questionable because the afferent loop fails to opacify in 20% of normal patients.⁹

Computed tomography (CT) is helpful in visualization of the obstructed afferent loop.⁹⁻¹¹ A characteristic finding on the CT is a dilated, U-shaped afferent loop that traverses the midline (Fig. 48-2). Nonopacification of the afferent loop is usual after oral contrast administration. Transmitted pressure from the obstruction may be sufficient to distend the gallbladder and bile

Figure 48-1 Afferent loop obstruction. Barium injection into small gastric remnant (S) results in preferential filling of a distended afferent loop (A). Only minimal contrast material enters the efferent (E) intestine. Distorted bowel margins are caused by kinking and tethering from adhesions (arrow).

Figure 48-3 Afferent loop obstruction after Roux-en-Y esophagojejunostomy. Coronal CT image displays obstructive distention of the afferent biliopancreatic limb (A) and common bile duct (arrow). The scan was performed with IV but without oral contrast media.

Figure 48-2 CT image of afferent loop obstruction. Oral contrast medium opacifies the normal efferent small bowel loops (E); the abnormal uniformly dilated afferent loop (A) remains nonopacified.

ducts.^{10,11} Coronal CT images aid in identifying the course of the obstructed loop and differentiating the intestine from other fluid collections (Fig. 48-3).⁶

Enterectomy and Anastomosis

Enterectomy refers to surgical excision of the intestine and its corresponding mesentery, as indicated by a wide variety of clinical conditions. Primary anastomosis generally follows

segmental resection of the small bowel, although in some patients an external ostomy is created in conjunction with closure or formation of a mucous fistula of the distal bowel segment.

Anastomosis of the small bowel is one of the most commonly performed GI surgical procedures because it is required for reconstituting continuity of the intestine after resection, bypassing an obstructed intestinal segment, and forming an enteric reservoir. Mechanical sutures and staples are established forms of instrumentation equal to the use of manual suturing techniques for all types of intestinal operations.¹²

Intestinal anastomoses can be constructed as an end-to-end, functional end-to-end (anatomic side-to-side), end-to-side, or side-to-side anastomosis (Fig. 48-4). An end-to-end anastomosis is preferred to reestablish continuity of the small bowel, provided there is minimal disparity in luminal size. An end-to-end anastomosis ideally serves to avoid small bowel stasis syndromes. Closing the two ends of an excised bowel segment and performing a side-to-side anastomosis in close proximity to the closed ends creates a functional end-to-end anastomosis that provides an increased anastomotic surface. An end-to-side anastomosis is used to compensate for disproportionate proximal and distal luminal sizes, and a side-to-side anastomosis is indicated in unusual clinical situations that require expeditious bypass of an intestinal obstruction (e.g., as with extensive neoplastic disease of the small bowel). When an end-to-side anastomosis is performed, the end of the proximal lumen is anastomosed to the side of the distal intestinal segment. This arrangement ensures that peristalsis within the blind (distal) segment is directed antegrade toward

Figure 48-4 Intestinal anastomoses. **A.** Functional end-to-end jejunal anastomosis, created by an anatomic side-to-side technique, is evident on enteroclysis with characteristic short oversewn ends (E) in close proximity to a broad anastomotic lumen (A) traversed by the catheter. **B.** Functional end-to-end anastomosis (arrow) demonstrated on a coronal CT enteroclysis image with similar anatomic features. E indicates oversewn ends of the proximal and distal loops. **C.** End-to-side anastomosis (arrow). **D.** Side-to-side anastomosis (arrow). (From Lappas JC, Maglinte DD: Imaging of the postsurgical small bowel. *Radiol Clin North Am* 41:305–326, 2003.)

and beyond the anastomotic opening, thereby preventing stasis (Fig. 48-5).¹

Despite careful preoperative patient preparation and meticulous surgical technique, dehiscence of small bowel anastomoses can occur. Aside from technical considerations, several factors may adversely affect the success of an anastomosis, including sepsis, tissue hypoxia, malignancy, and advanced patient age. Intestinal perforation from an anastomotic dehiscence may be detected by the presence of free intraperitoneal air on abdominal radiographs. Contrast studies performed with water-soluble contrast media may demonstrate an intestinal leak, although similar findings are detectable on CT, which also provides the advantage of localizing contaminated peritoneal fluid and imaging the complication of abscess formation. Extraintestinal fluid collections, which progressively increase in volume in the postoperative period, are suggestive of an anastomotic disruption, and evidence of enteric contrast media extravasation is diagnostic. Suture dehiscence with a small or contained intestinal leak can also result in a localized

perianastomotic inflammatory process or phlegmon, which may result in partial intestinal obstruction (Fig. 48-6).

POSTOPERATIVE BLIND POUCH AND LOOP

Although the anatomic end-to-end and functional end-to-end surgical anastomoses have essentially replaced the side-to-side anastomosis to restore bowel continuity, the latter procedure is occasionally performed, and a postoperative blind pouch may develop. It should be appreciated that a blind pouch is not intentionally created, unlike a postoperative blind loop. During side-to-side anastomosis, division of the circular muscle can result in local dysmotility with stasis that leads to progressive dilation of the proximal anastomotic segment and formation of a blind intestinal pouch. An incorrectly performed end-to-side anastomosis (side of the proximal segment of intestine sutured to the end of the distal intestine) creates a similar anatomic abnormality. Occasionally, blind pouches may be encountered in association with a prior functional end-to-end (anatomic

Figure 48-5 End-to-side anastomosis. A. Using correct surgical technique, the end of the proximal small bowel segment is anastomosed to the side of the distal small bowel segment, allowing intestinal contents to flow in a normal peristaltic direction (arrows) through a patent bowel lumen. **B.** An improper anastomosis, with the side of the proximal bowel segment sutured to the end of the distal bowel segment, allows intestinal peristalsis (arrows) to be directed into the blind segment and contributes to the complication of lumen dilation (pouch formation) and intestinal stasis.

side-to-side) surgical anastomosis because of abnormal local peristalsis and stasis.

In addition to intestinal stasis with potential for bacterial overgrowth, a postoperative blind pouch can be associated with inflammation, ulceration, and intestinal bleeding.¹³ Symptoms of abdominal pain and distention, episodic diarrhea, and a history of previous intestinal anastomosis suggest the clinical syndrome and its underlying abnormality, but diagnostic confirmation requires radiologic imaging. Segmental pouch resection and a restorative end-to-end anastomosis are corrective and eliminate the associated complications.

On CT, an intestinal blind pouch is recognized as a distinct saccular enteric structure, with surgical clips visible in the adjacent region.¹⁴ Small bowel contrast studies, particularly enteroclysis and CT enteroclysis, demonstrate the pouch and its anastomotic relationships (Fig. 48-7).

Although some clinical features are in common with the blind pouch syndrome, the anatomic abnormality associated with the blind loop syndrome is different. In blind loop syndrome, a segment of small intestine has been completely bypassed from the enteric stream by an enteroanastomosis. Stagnation of small bowel contents within the blind loop leads to bacterial overgrowth, which, in the most severely affected patients, can approximate the composition of normal colonic

Figure 48-6 Perianastomotic phlegmon with intestinal narrowing. Symptoms of obstruction developed in this patient shortly after a segmental ileal resection with end-to-end anastomosis was performed for benign disease. Enteroclysis shows a short segment of luminal narrowing with a small leak (white arrow) and thickened folds (black arrows) of the adjacent ileal loop. At surgery, ischemic dehiscence of the anastomosis was associated with a localized inflammatory reaction and mural edema of the proximal bowel segment.

Figure 48-7 Blind pouch. CT enteroclysis shows formation of a sacular blind pouch (P) associated with a prior side-to-side jejunal anastomosis. Arrows point to the afferent and efferent limbs.

flora in quantity and complexity of organisms. Bacterial overgrowth in the small intestine may result in profound disturbances of absorptive function, with malabsorption of lipids and vitamin B₁₂ being most notable.¹⁵ Symptoms and clinical signs of the syndrome are those of malabsorption and include

diarrhea, steatorrhea, anemia, and nutritional deficiencies. As in the diagnosis of blind pouch, dedicated small bowel enteroclysis studies can accurately demonstrate the postoperative anatomic abnormality.

Enterostomy

Enterostomy refers to an intestinal opening that is surgically designed to communicate with the skin and function on a temporary or permanent basis. To prevent an intra-abdominal leak from the intestinal lumen, an enterostomy is made in small bowel segments that are sufficiently mobile to be brought into contact with the anterior abdominal wall.

JEJUNOSTOMY

Jejunostomy is an ideal route for administering nutritional support.¹ Advantages of a feeding jejunostomy over gastrostomy include reduced nausea, vomiting, and risk of pulmonary aspiration via gastroesophageal reflux. Surgical feeding jejunostomies are performed in malnourished patients with an anticipated lengthy postoperative course, in patients with pathology of the upper GI tract, including gastroparesis, malignancy, fistula, and anastomotic leaks proximal to the potential jejunostomy site, and in patients who are not candidates for endoscopic, fluoroscopic, or laparoscopic insertion of feeding jejunostomies or who have failed these approaches. Direct intubated jejunostomies satisfy temporary nutritional requirements, whereas long-term jejunal feeding is best accomplished by a Roux-en-Y type jejunostomy. Surgical placement of the jejunostomy, at least 70 cm distal from the duodenojejunal junction and fixation of the jejunal loop to the peritoneum, are common precautions used during jejunostomy construction. Some surgeons prefer injection of the jejunostomy catheter with a water-soluble contrast medium before initiating enteric feeding to ascertain proper catheter position and thus avoid a misdirected infusion.

Various complications can be associated with any of the surgical jejunostomy methods.^{1,16} In a series of patients with jejunostomy tubes, radiologic studies demonstrated complications related to catheter placement in 14% of cases; in 19% of cases, various mechanical problems were attributed to the location or function of the catheter.¹⁷ Abnormalities included enterogastric reflux of the alimentary fluid, malposition of the catheter, and dislodgment, with an intra-abdominal leak and small bowel obstruction at or near the jejunostomy site.

ILEOSTOMY

A distal enterostomy or ileostomy is primarily used for evacuation of intestinal contents in clinical situations that preclude normal use of the colon or require its surgical removal. A conventional (end) ileostomy, with total proctocolectomy, provides a relatively simple and often curative surgical approach that mitigates the future risks of malignancy or recurrent inflammation with these diseases. The loss of fecal continence and its attendant physical and psychological effects remain significant drawbacks of ileostomy surgery. Since the development of the ileoanal reservoir procedures, the use of conventional ileostomy has been restricted to patients with extensive Crohn's proctocolitis, anal sphincter dysfunction, reservoir failure, and older

Figure 48-8 Parastomal hernia. This 51-year-old woman had a history of pelvis leiomyosarcoma requiring distal colonic resection and left lower quadrant colostomy. The CT image shows a large anterior abdominal wall defect with herniation of multiple small bowel loops and mesentery (arrow). The colon (c) proximal to the ostomy (o) is displaced to the side. This diagnosis requires careful review of several scan slices because the herniated loops and stoma are often in different axial scan planes.

patients.¹⁸ Another form of distal enterostomy, the loop (double-barrel) ileostomy, is performed in some situations to permit temporary intestinal diversion. Circumstances include Crohn's disease complicated by abscess or extensive fistulas and emergency intervention for intestinal obstruction, or as an adjunct to complex operations that require the protection of a distal enteric anastomosis to promote healing.

Creation of a conventional Brooke or everted end-ileostomy involves transection of the ileum with mobilization of a 5-cm ileal segment through an abdominal wall defect and a specific suturing technique to allow for ileostomy maturation.¹⁸ Malfunction of an ileostomy may result from adhesions, prestomal narrowing of the ileal lumen, paraileostomy herniation, and recurrent disease. These abnormalities can present early or late after operation and usually occur at or near the ileostomy site, producing symptoms of diarrhea or intestinal obstruction.

CT accurately detects parastomal hernias because it is the most commonly performed examination in patients with unexplained stoma-related abdominal symptoms. Herniation is often associated with large (>3-cm) defects in the anterior abdominal wall at the stomal site and is common lateral to the stoma (Fig. 48-8).¹⁹ Evaluation of patients with an ileostomy and suspected ileostomy dysfunction or other complication can also be safely performed by retrograde contrast media examinations, including enteroclysis.

Ileal Reservoirs

Ileal reservoirs are continence-preserving surgical procedures that offer patients the advantage of an improved body image and active lifestyle. Many surgeons consider the presence of Crohn's disease a contraindication for these procedures because of the increased risk for recurrent inflammatory disease and the potential for additional small bowel resection in these patients.¹⁸

CONTINENT ILEOSTOMY RESERVOIR

Kock introduced the concept of an internal reservoir associated with a postcolectomy ileostomy in 1969 and demonstrated that the terminal ileum could function as a low-pressure, highly compliant reservoir.²⁰ The complexity of Kock pouch construction and function now limits the application of the procedure to select patients with prior colectomy and conventional ileostomy or failed or contraindicated ileoanal pouch surgery.^{18,21}

Creation of a continent ileostomy involves the use of the distal 45 cm of ileum, with the most proximal ileal segment fashioned into a spherical reservoir by complex suturing techniques. By design, opposing directions of peristalsis prevent propulsive activity from emptying the pouch. Continence is further maintained by intussusception of the efferent ileal segment into the pouch to form the valve mechanism; the end of the ileum creates the abdominal wall stoma. Suturing of the pouch to the anterior abdominal wall provides stability and prevents volvulus of the pouch and peripouch herniation. Successful Kock pouch construction obviates the use of an external ileostomy appliance because the contents of the ileal reservoir are evacuated by stomal intubation.

Complications of the Kock pouch usually occur months after surgery and include various forms of valve dysfunction, non-specific inflammation of the reservoir or the afferent ileal segment (pouch ileitis), and fistulas. Although reasonable functional results, including long-term continence, are achieved, the incidence of surgical revision in patients with a continent ileostomy remains high.²²

Retrograde double-contrast barium examination following cleansing irrigation of the reservoir is the recommended method for evaluation of the Kock pouch.²³ Radiography in an oblique or lateral view is required to visualize the efferent ileal segment and ileostomy stoma adequately. Suspicion of suture dehiscence in the immediate postoperative period or pouch perforation, after intubation, should be evaluated using water-soluble rather than barium contrast media.

Barium studies of the normal reservoir show typical small bowel fold patterns interrupted by a linear mucosal ridge that represents the suture line between the two anastomosed ileal segments.²³ Surface granularity is seen with mild pouchitis, whereas ulceration and mucosal fold distortion occur with more severe pouch inflammation.²⁴ The intact continence valve appears as a tubular or round, lobular structure invaginated within the reservoir and associated with an array of stabilizing surgical clips. Sliding and eversion of the valve from the pouch results in valve shortening, with progressive lengthening and tortuosity of the efferent ileal segment to the stoma.²⁴ Difficulty in pouch intubation, chronic outflow obstruction, and incontinence ensue. Adenomas may occur in the continent ileostomy, and surveillance of the reservoir is required for patients who have undergone surgery for familial polyposis syndromes (Fig. 48-9).

ILEOANAL POUCHES

Creation of an ileal reservoir with an ileoanal anastomosis following colectomy and rectal mucosectomy has become an important surgical alternative for patients requiring total proctocolectomy. In patients with primary colonic mucosal disease, including chronic ulcerative colitis and adenomatous polyposis, this innovative operation removes potential disease-bearing

Figure 48-9 Kock pouch in a patient with familial adenomatous polyposis. Contrast medium injection of the pouch (P) after catheterization of the efferent limb shows multiple round mucosal defects representing recurrent adenomas. An irregular mass (arrow) suggests malignancy. A, afferent limb.

mucosa while preserving anal continence and the normal defecatory pathway.

Several forms of ileoanal pouch have been described, but the J pouch configuration is preferred because of the simplicity of its construction, adequate reservoir capacity, ease of emptying, and absence of a potentially obstructing efferent limb.^{18,25} An ileoanal J pouch is constructed from the distal 25 cm of ileum, fashioned into a J shape, and secured by side-to-side anastomosis of the two adjacent loops (Fig. 48-10A). After anorectal mucosectomy and rectal transection that spares the integrity of the anal sphincter, the constructed ileal pouch is anastomosed to the dentate line of the rectal cuff. A proximal diverting ileostomy is often established for 8 to 12 weeks to allow for healing of the extensive anastomoses, and eventual closure of the protective ileostomy renders the ileoanal pouch functional.

Although excellent functional results can be achieved in patients with an ileoanal reservoir, the procedure may be associated with significant complications.^{26,27} Common problems include pouchitis, small bowel obstruction, anastomosis dehiscence or stricture, fistula, and pelvic abscess. Most complications are adequately managed, but ileoanal pouch failure can occur in up to 10% of patients.²⁶ Radiologic evaluation of the ileoanal reservoir is required to assess its function and exclude anastomotic leakage from the reservoir and other postoperative complications.²⁸⁻³¹

Postoperative imaging of the ileoanal pouch is not routinely performed but reserved for clinically suspected complications.³² Contrast ileography or pouchography can be performed antegrade through the ileostomy stoma or preferably retrograde via a soft rectal catheter to visualize the ileoanal pouch and anastomosis. Water-soluble contrast media is used for early

Figure 48-10 Ileoanal-J pouch. **A.** Schematic representation showing side-to-side anastomosis of the adjacent ileal loop and direct anastomosis of the inferior apex of the reservoir to the dentate line. **B.** Normal pouchogram with characteristic vertical raphe (arrows) created by the anastomotic line. **C.** CT image of normal pouch (P) with surrounding ileal mesentery (short arrow) and thin muscular anorectal wall (long arrow). (From Lappas JC, Maglinte DD: *Imaging of the postsurgical small bowel*. *Radiol Clin North Am* 41:305–326, 2003.)

postoperative examinations or if there is an abnormal clinical examination of the pouch; otherwise, barium is used for routine evaluations. On contrast studies, the normal J pouch is depicted as an ovoid intestinal structure with distinctive vertical raphes that correspond to the line of anastomosis, whereas on CT, a thin surgically stapled pouch wall is demonstrated, with adjacent normal fat (Fig. 48-10B and C).^{28,29}

Pouchitis or mucosal inflammation of the ileoanal pouch occurs in almost 50% of patients undergoing the procedure and presents as a clinically evident syndrome of fever, abdominal cramping, and diarrhea. Contrast pouchograms are non-specific but may demonstrate spasm and thickened ileal pouch folds. In patients with anastomotic dehiscence and pelvic sepsis, pouchograms may demonstrate abnormal findings, such as contrast extravasation, extraluminal gas, thickening and spiculation of pouch folds, and mass effect. On CT, patients with postoperative pelvic infections demonstrate abnormal pouch and rectal wall thickness in addition to inflammatory infiltration of the peripouch and perirectal fat. Abscesses typically occur in the peripouch region between the ileal mesenteric fat and adjacent rectal muscularis (Fig. 48-11). In patients with infectious complications after ileoanal pouch surgery, the findings on ileography are often nonspecific, whereas CT more accurately delineates the inflammatory process and can also direct therapeutic intervention.^{29,31} Later complications of intestinal obstruction manifest after closure of the ileostomy and commonly involve the closure site or distal small bowel. Adhesions, volvulus, and anastomotic stricture are often problematic because of the extensive surgical resection and bowel manipulations.^{25,26}

Small Bowel Transplantation

Intestinal transplantation has come of age for the past 3 decades and now offers hope of long-term survival in patients with life-threatening complications of intestinal failure and parenteral nutrition. Success rates have greatly improved, largely through advances in immunosuppression protocols,

improved surgical technique, postoperative care, and accumulated experience. Approximately 2500 intestinal transplantations have been performed worldwide at over 75 centers, and graft survival rates are reaching 80% at 1 year and 50% at 5 years at experienced centers.³³ More than 80% of all current survivors have stopped parenteral nutrition and resumed normal daily activities.

Intestinal failure may result from surgical or anatomic loss of intestine (short bowel syndrome) or from a significant functional abnormality. Conditions treated by small bowel transplantation include volvulus, necrotizing enterocolitis, and intestinal atresia in children and vascular disorders, Crohn's disease, and intestinal trauma in adults. Total parenteral nutrition (TPN), the primary treatment for most patients with intestinal failure, can also lead to life-threatening hepatic failure. These factors also influence the decision to transplant and the specific transplantation procedure used.³⁴

Three types of transplantation operations are performed.^{34,35} Isolated intestinal transplantation is performed in patients who maintain good hepatic function (Fig. 48-12). Combined intestinal and liver transplantation is done in those with TPN-related or inborn hepatic dysfunction. Multivisceral transplantations (intestine, liver, stomach, duodenum, and pancreas) comprise approximately 24% of adult transplantation procedures and are reserved for patients with extensive GI tract abnormalities caused by vascular, absorptive, or motility disorders.³⁴ In small bowel transplantation, a donor intestine is anastomosed to the recipient colon, with the creation of a diverting ileostomy; this can be closed a few months after transplantation following stabilization of the patient and the absence of graft rejection or infection. Current surgical practice usually excludes the colon from intestinal allografts.

Prior to intestinal transplantation, prospective candidates undergo a series of radiologic examinations to address a variety of clinical issues.^{36,37} GI contrast examinations are used to assess the nature and extent of bowel abnormality

Figure 48-11 Peripouch abscess. A. J pouch ileogram demonstrates an anastomotic breakdown (thin arrow) with extravasation of water-soluble contrast media (thick arrow). Adjacent pelvic inflammation results in lumen narrowing and irregularity of the pouch (P). **B.** CT image defines a large multilocular abscess (A) that encircles the collapsed pouch and its fat density mesentery (arrow). Inflammation creates rectal wall thickening and stranding into the perirectal fat. (From Lappas JC, Maglinte DD: *Imaging of the postsurgical small bowel*. *Radiol Clin North Am* 41:305–326, 2003.)

Figure 48-12 Schematic representation of isolated small bowel transplantation (donor intestine shaded). After critical donor-recipient arterial and venous anastomoses are established, the intestinal graft is anastomosed to the recipient colon with a temporary ileostomy.

and, in patients with short bowel syndrome, to map the amount of remaining intestine. After transplantation, contrast studies can be used to evaluate anastomoses, obstruction, fistulas, gastric emptying, intestinal transit, and small bowel mucosal patterns. Postsurgical anatomy includes a native to donor jejunojejunal, duodenojejunal, or gastrogastrostomy and a donor to native ileocolic anastomosis with an end-ileostomy. Healthy allografts show normal bowel caliber and mucosal patterns, active peristalsis, and normal transit times.

Abnormalities on early postoperative GI contrast studies include gastric atony and slow small bowel transit, with varying degrees of lumen dilation.³⁶ Edematous thickening of graft mucosal folds may be present early after operation because of harvesting injury. Fold thickening seen later in the postoperative period raises the suspicion of infection, rejection, or ischemia.³⁶ Loss of the normal fold pattern, resulting in a tubular appearance of the intestinal graft, may be caused by acute and chronic rejection and infection with cytomegalovirus (Figs. 48-13 and 48-14). However, radiologic studies are insensitive

Figure 48-13 Small bowel transplant rejection. Unenhanced CT image in a 60-year-old woman with a history of small bowel transplantation. Small bowel loops within the right lower quadrant showing loss of bowel fold pattern and diffuse thickening (arrow). There is also mesenteric edema and a small amount of free fluid. The patient had a small bowel biopsy, and acute rejection was diagnosed.

Figure 48-14 Small bowel transplant rejection. Patient who is status post-multivisceral transplantation presented with persistent nausea and vomiting. Image from an upper GI examination shows loss of mucosal folds in the proximal jejunum (short arrows). The pylorus shows luminal narrowing (long arrow), resulting in partial gastric outlet obstruction.

for the detection of acute graft rejection or infection, which are diagnosed using frequent surveillance ileoscopy with mucosal biopsy and zoom video endoscopy.³⁵

Indications for post-transplantation CT imaging are suspected abdominal infection, hemorrhage, hepatic abnormality, or post-transplantation lymphoproliferative disorder (PTLD).

On CT, uncomplicated small bowel grafts demonstrate non-dilated intestinal loops with normal wall thickness and patency of the critical vasculature.³⁸ Varying degrees of intra-abdominal fluid are common in the early postoperative period and consist of interloop ascites or loculated fluid collections, with or without infection. Abnormalities on CT may include intestinal dilation associated with ileus or obstruction and nonspecific bowel wall thickening caused by preservation injury, graft

rejection, infection, and ischemia. CT can delineate the spectrum of findings related to anastomotic leaks, thrombosis of arterial or venous grafts, PTLD, and complications specific to liver transplantation.^{36,38} PTLD is more common in intestinal transplantation than in other organ transplantations because of the degree of immunosuppression. Manifestations of PTLD include abdominal lymphadenopathy and solid masses of the intestinal tract and solid organs.

Miscellaneous Abnormalities of the Small Bowel

STEPHEN E. RUBESIN

CHAPTER OUTLINE

Abnormalities of Small Bowel Development in Adults

Meckel's Diverticulum

Midgut Duplications

Heterotopic Tissue

Segmental Dilation

Intestinal Malrotation

Paraduodenal (Mesocolic) Hernias

Endometriosis

Intestinal Edema

Enteroliths and Bezoars

Abnormalities of Small Bowel Development in Adults

MECKEL'S DIVERTICULUM

The yolk sac provides nutrition to the fetus before the placenta develops. The yolk sac is connected to the midgut by the omphalomesenteric duct (vitellointestinal duct). This duct is obliterated during the seventh to eighth weeks of embryogenesis as the placenta assumes the nutritional feeding of the fetus.¹ Persistence of various portions of the omphalomesenteric duct leads to a variety of anomalies. Failure of the entire omphalomesenteric duct to atrophy leads to an enteroumbilical fistula. Failure of one portion of the duct to atrophy may result in a fusiform area of dilation, termed an *omphalomesenteric cyst*. Persistence of the vitellointestinal duct as a fibrous cord can lead to volvulus or compressive obstruction.

Meckel's diverticulum results from persistence of the omphalomesenteric duct at its attachment to the ileum. It is the most common congenital abnormality of the gastrointestinal (GI) tract; the prevalence of Meckel's diverticulum at autopsy is 1% to 4%.^{2,3} However, most people with this congenital anomaly never develop symptoms.

Meckel's diverticulum arises from the antimesenteric border of the ileum, usually within 100 cm of the ileocecal valve. It may be connected to the umbilicus by a fibrous band or to other intestinal loops by congenital bands or adhesions. The diverticulum usually varies from 2 to 15 cm in length and is about 2 cm in width.¹ Meckel's diverticulum contains all layers of the intestinal wall. The diverticulum is lined by small bowel epithelium and often contains heterotopic gastric or pancreatic tissue or Brunner's glands.¹

Infants (<2 years) with Meckel's diverticulum may present with GI bleeding caused by secretion of acid by ectopic gastric

mucosa and subsequent ulceration. Adults may present with GI bleeding, obstruction, or perforation.⁴⁻⁷ Diverticulitis results from ulceration and focal perforation of the diverticulum caused by ectopic gastric mucosa or an enterolith or foreign body impaction.⁸ Obstruction results from a variety of mechanisms, including intussusception, volvulus around a persistent fibrous or adhesive band, and ileal narrowing related to ulceration. The diverticulum may become incarcerated in an inguinal, femoral, or umbilical hernia, also known as a Littre hernia.⁹ A variety of tumors may arise in Meckel's diverticulum, including carcinoid tumors, adenocarcinomas, and benign or malignant mesenchymal tumors.¹⁰

Technetium pertechnetate scintigraphy can detect ectopic gastric mucosa in more than 85% of infants, children, and adults with Meckel's diverticulum who have acute or chronic GI bleeding.^{5,11-13} However, most adults are asymptomatic or develop symptoms related to obstruction. All imaging modalities (except enteroclysis) have poor sensitivity for the detection of Meckel's diverticulum. In a small percentage of cases, plain abdominal radiographs may reveal radiopaque enteroliths in a Meckel diverticulum^{14,15} or a dilated, gas-filled diverticulum in the right lower quadrant. Meckel's diverticulum is rarely diagnosed on small bowel follow-throughs, except in patients with excessive mesenteric fat related to obesity or Crohn's disease.^{16,17} Computed tomography (CT) or ultrasound may demonstrate a cystic or tubular structure attached to bowel in the right lower quadrant.

In adults without GI bleeding, enteroclysis is the best radiologic test for Meckel's diverticulum. A Meckel's diverticulum is detected in 2% to 3% of all patients undergoing enteroclysis, approaching the incidence at autopsy.¹⁸⁻²⁰ A blind-ending tubular or cystic sac (Fig. 49-1) is usually seen to communicate with the antimesenteric border of the distal ileum.²¹ One clue to the presence of the diverticulum is a triradiate fold pattern at the junction of the sac with the intestinal lumen. Folds in the diverticulum will be perpendicular to folds in the adjacent ileum. The surface of the diverticulum may be abnormal, containing a granular mucosa, focal ulceration, or focal polypoid mound of ectopic gastric mucosa or tumor. In other patients, an inverted Meckel diverticulum may appear as a polypoid intraluminal lesion (Fig. 49-2), which sometimes acts as lead point for a small bowel intussusception.²¹⁻²⁴

MIDGUT DUPLICATIONS

Small bowel duplication is a congenital incomplete or complete doubling of a variably long segment of bowel.² The duplication may be served by an independent mesentery or by the same mesentery as the adjacent bowel. Midgut duplication cysts contain all layers of the bowel wall, including a mucosa, submucosa, and inner circular muscle layer, with its

Figure 49-1 Meckel's diverticulum. A spot image when the diverticulum was incompletely distended shows a triangular sac (*thick arrow*) arising from the distal ileum. Smooth folds (*thin arrow*) radiate to the origin of the diverticulum. Note how this Meckel's diverticulum appears to arise from the concave border of the bowel. This image demonstrates how the concave border of a small bowel loop is not always its true mesenteric border because Meckel's diverticulum arises from the antimesenteric border of the ileum.

associated myenteric plexus.¹ Some duplications have a full longitudinal muscle layer, and others have no longitudinal muscle.² The mucosal lining of these cysts is usually intestinal. Duplication cysts may also contain gastric mucosa, pancreatic tissue, thyroid stroma, ciliated bronchial epithelium, lung, and cartilage.¹

Most midgut duplications involve the ileum, particularly the region of the ileocecal valve, and the duodenum. These are usually elongated lesions attached to the muscular layer of the adjacent small bowel. If secretions accumulate, the duplication may become a cystic mass protruding into the small bowel mesentery. Multiple duplications are found in about 5% of patients.^{25,26} Approximately 20% of these duplications communicate with the bowel lumen at the proximal or distal end of the cyst or at both ends.²⁷

Ectopic gastric epithelium lining a duplication cyst may cause peptic ulceration, with subsequent GI bleeding or perforation.²⁸ Obstruction may result from volvulus, intussusception, or compression of the adjacent bowel by the cyst. Rarely, duplication cysts are complicated by tumor.

Duplication cysts may be manifested on barium studies by an extrinsic mass indenting and compressing the mesenteric border of the adjacent bowel.²⁹ Barium enters the cyst in only a small percentage of cases (*Fig. 49-3*). CT or ultrasound may show a cystic mass embedded in the small bowel wall.^{29,30} If there is concern about GI ulceration or bleeding, a ^{99m}Tc-pertechnetate scan usually reveals heterotopic gastric mucosa in the cyst.

Figure 49-2 Inverted Meckel's diverticulum. Enteroclysis shows a long, smooth-surfaced, polypoid intraluminal filling defect (*closed arrow*) in the distal ileum. A tubular radiolucent filling defect (*open arrow*) resembles a stalk. This inverted Meckel's diverticulum could be mistaken for a pedunculated ileal polyp, such as a lipoma or inflammatory fibroid polyp. (From Rubesin SE, Herlinger H, DeGaeta L: *Test your skills. Inverted Meckel's diverticulum. Radiology 176:636, 644, 1990.*)

HETEROTOPIC TISSUE

Ectopic gastric mucosa is present in a wide variety of locations in the GI tract, including the esophagus, duodenum, and mesenteric small intestine, as well as in congenital abnormalities such as duplication cysts and Meckel's diverticulum. Congenital ectopic mucosa contains an orderly arrangement of superficial foveolar epithelium and underlying fundic glands partially lined by parietal and chief cells.³¹ Ectopic mucosa should be distinguished from the more common foveolar metaplasia found in the duodenal bulb in patients with peptic duodenitis.³² However, foveolar metaplasia in peptic duodenitis lacks organized gastric pits and glands.¹

Ectopic pancreas is most frequently encountered in the duodenum (28%), stomach (26%), or jejunum (16%).³³ The ectopic tissue may arise in various levels of the bowel wall, including the mucosa, submucosa, and serosa.³¹ Ectopic pancreatic tissue is composed of varying numbers of acini, ducts, and islet cells. Ectopic pancreas has also been reported in jejunal and ileal diverticula and Meckel's diverticulum, as well as in the gallbladder, bile ducts, umbilicus, and fallopian tubes.

Ectopic pancreas in the mesenteric small bowel is usually discovered incidentally as a nodule or mass of lobulated solid or cystic tissue abutting the bowel in patients operated on for other reasons. Although microscopic pancreatitis is not uncommon, clinical pancreatitis is very unusual. One case of ectopic pancreas in the jejunum has been reported in which the patient developed pancreatitis and pseudocyst formation.³⁴ In this patient, a cystic lesion abutted a jejunal loop, mimicking jejunal diverticulitis or a small perforated tumor (Fig. 49-4).

SEGMENTAL DILATION

The small intestine may have a focally dilated, aperistaltic segment, termed *segmental dilation*.^{35,36} In most cases, the

Figure 49-3 Duodenal duplication. Barium fills a 10-cm cavitory lesion that parallels the inner border of the third and fourth portions of the duodenum. The adjacent duodenum has normal folds. It is difficult to distinguish this duplication from an exophytic cavitory mass, such as a gastrointestinal stromal tumor (arrows). (Courtesy Hans Herlinger, MD.)

isolated atonic loop is in the ileum, giving rise to the term *ileal dysgenesis*. The cause of this condition is uncertain, but it has been postulated that it results from congenital neuromuscular dysfunction. Ganglion cells are present.² In children, ileal dysgenesis is associated with Meckel's diverticulum and omphaloceles.^{37,38} Ectopic mucosa (especially gastric mucosa) may be found in the dilated segment and may cause ulceration.

Segmental dilation may be manifested on barium studies by a focally dilated spherical or tubular segment of ileum (Fig. 49-5) in direct contiguity with the adjacent inflow and outflow loops of ileum.³⁹ The aperistaltic segment functions as a barrier to intestinal flow, resulting in partial small bowel obstruction. Ulcerated mucosa may be present in some patients. This condition can be distinguished from Meckel's diverticulum by its direct continuity with adjacent ileal loops. Ileal dysgenesis can also be distinguished from primary small bowel lymphoma with aneurysmal dilation by the normal mucosal surface of the dilated ileal loop.

INTESTINAL MALROTATION

Symptomatic patients with intestinal malrotation are usually infants and children with high-grade obstruction caused by midgut volvulus or Ladd's bands. The embryologic, clinical, and radiographic aspects of intestinal malrotation in infants and children are described in detail in Chapters 113 and 116. Adults with intestinal malrotation are usually asymptomatic or have vague abdominal complaints.⁴⁰⁻⁴²

The midgut is that portion of bowel related to the superior mesentery artery and vein axis; it is composed of the third and fourth portions of the duodenum, jejunum, ileum, cecum, appendix, ascending colon and transverse colon. Intestinal malrotation encompasses a number of variations based on the degree of rotation of the midgut in the umbilical cord and degree of rotation when and after it returns to the coelomic cavity. The variations include nonrotation, malrotation, hyperrotation, and reversed rotation.

During the eighth fetal week, the midgut loop rotates 90 degrees counterclockwise while it is within the umbilical cord, so that the cecum lies on the left side of the fetus and the

Figure 49-4 Ectopic pancreas in the jejunum complicated by pancreatitis and pseudocyst formation. **A.** Enteroclysis shows a tiny barium collection (short arrow) in the jejunum. Small bowel folds in this region are mildly thickened and undulating (long arrow) and are parallel to the longitudinal axis of the bowel rather than straight and perpendicular to the bowel, as seen in the normal adjacent jejunum. Mass effect (open arrows) is also seen at the edge of the lesion. **B.** CT scan shows a soft tissue mass (long arrow) replacing the contrast-filled lumen of the bowel. A central cavity (short arrow) contains air and soft tissue. At pathology, the soft tissue mass was ectopic pancreatic tissue with associated pancreatitis, and the cavity was a pseudocyst that communicated with the lumen. This lesion could easily be confused with jejunal diverticulitis or a cavitory mass, such as lymphoma.

Figure 49-5 Ileal dysgenesis. Enteroclysis shows a large bilobed ileal segment (arrows). Normal entry and exit loops of pelvic ileum were seen on other views.

jejunum on the right.¹ If the midgut returns to the abdomen without further rotation, it maintains this orientation. Although this variation represents a 90-degree rotation, it has been confusingly termed *nonrotation* because the small bowel is not rotating within the coelomic cavity. Nonrotation actually represents small bowel rotation that stopped at 90 degrees of counterclockwise rotation within the umbilical cord. The third and fourth portions of the duodenum and duodenojejunal flexure are absent. Instead, the jejunum is in direct continuation with the second portion of the duodenum (Fig. 49-6). The jejunum and ileum lie in the right side of the abdomen, whereas the colon lies on the left side. The cecum is in the midline, with the terminal ileum entering the cecum from its right side. The appendix originates from a midline position, often low in the midline of the abdomen.⁴³

During the 10th fetal week, the midgut normally rotates another 90 degrees counterclockwise within the umbilical cord, so that the cecum lies superiorly on the right and the jejunum inferiorly on the left.⁴³

The jejunum is then the first midgut section to reenter the coelomic cavity, passing behind the superior mesenteric artery. During this part of rotation in the coelomic cavity, the jejunum comes to lie between the posteriorly located duodenum and anteriorly positioned colon. During the 11th week, the cecum rotates still another 90 degrees into the right lower quadrant, completing a 270-degree counterclockwise rotation.

Intestinal malrotation occurs when the midgut fails to complete its 180-degree counterclockwise rotation after the initial 90-degree rotation in the umbilical cord. The duodenojejunal junction is not fixed in its normal location to the left of the spine but instead lies inferiorly and to the right of the spine. The small bowel lies predominantly in the right or midabdomen. Mesenteric bands from the liver and posterior abdominal wall cross the second portion of the duodenum and extend to the cecum (Ladd's bands).

Figure 49-6 Intestinal nonrotation. This overhead radiograph from small bowel follow-through shows the duodenal bulb (d) in a normal location, with lack of the third and fourth portions of the duodenum and lack of a duodenojejunal junction to the left of the spine. The jejunum (j) is in the right upper quadrant, and most of the ileum is also in the right abdomen, with the distal ileum (i) crossing to the left to join a midline cecum (C). The colon lies in the left abdomen.

Intestinal hyperrotation occurs when the small intestine has rotated more than the usual 180 degrees, resulting in a long ascending colon, with the cecum located in the left upper quadrant. In a reversed rotation, the bowel enters the abdomen with a clockwise rotation, so the transverse colon lies posterior to the duodenum in the right upper quadrant.

Rather than being confused by the series of somewhat misnamed rotational terms, the radiologist can focus on the following: (1) how much duodenum is present; (2) the location of the duodenal-jejunal junction; (3) the anterior-posterior relationship of the jejunum and ileum to the transverse colon and duodenum; (4) the location of the cecum and the relationship of the appendix and ileocecal valve to the cecum; (5) the location and length of the ascending colon; and (6) the relationship of the superior mesenteric artery (SMA) to the superior mesenteric vein (SMV).

The location of the duodenojejunal junction should be ascertained in any adult with vomiting or abdominal pain. The normal duodenojejunal junction lies to the left of the spine, at about the level of the duodenal bulb. When the ligament of Treitz is in its normal position, the first loops of the jejunum may cross to the right of the spine as a normal variant—as long as the jejunum is not entering a posteriorly located right paraduodenal hernia. On the other hand, the duodenojejunal junction not infrequently has an abnormal location. An abnormally positioned duodenojejunal junction is important because it may cause twisting and obstruction of the proximal small

Figure 49-7 Intestinal malrotation. Axial CT through the tip of the liver shows that the superior mesenteric vein (*long arrow*) lies anterior and to the left of the superior mesenteric artery (*short arrow*). The jejunum (s) lies in the right upper quadrant.

bowel, manifested by duodenal dilation and slow transit of contrast material on barium studies. However, the typical corkscrew sign of intestinal malrotation and midgut volvulus in infants (see Chapter 113) is rarely found in adults.⁴⁴ Intestinal malrotation in adults is often recognized on CT, magnetic resonance imaging (MRI), or ultrasound by an abnormal relationship between the SMA and SMV, so that the vein lies anterior and to the left of the artery (Fig. 49-7).

PARADUODENAL (MESOCOLIC) HERNIAS

Paraduodenal hernias are the most common internal abdominal hernias, accounting for about 50% of all such hernias. Although abdominal hernias are discussed in detail in Chapter 112, paraduodenal hernias are discussed here because these hernias relate to abnormal rotation and fixation of the colonic mesentery to the retroperitoneum.^{45,46}

A left paraduodenal hernia represents a hernia of the proximal jejunum into the mesentery of the descending colon. The opening of a left paraduodenal hernia is just lateral to the fourth portion of the duodenum at the fossa of Landzert, an anatomic fossa found at autopsy in 2% of patients.⁴⁷ This fossa is present when the inferior mesenteric vein and ascending left colon artery are incompletely fixed to the retroperitoneum. Loops of jejunum can herniate beneath the mesentery of the descending colon, potentially causing small bowel obstruction or ischemia.

A left paraduodenal hernia may be manifested on barium studies by a variable number of jejunal loops clumped together in the left upper quadrant lateral to the fourth portion of the duodenum (Fig. 49-8). The inlet and outlet loops may be focally narrowed where they are compressed at the hernia orifice (see Fig. 49-8). The loops do not change position with time or palpation because they are fixed within the hernia sac. Barium may be retained in these loops on delayed images because of obstruction. Abdominal CT may reveal a cluster of small bowel loops lateral to the duodenum, between the adrenal gland and transverse or descending colon.⁴⁸ The proximal jejunum lies posterior to the inferior mesenteric vein (IMV) vessels and behind and lateral to the descending colon.

Figure 49-8 Left paraduodenal hernia. This coned-down image from overhead radiograph on enteroclysis performed via a Kantor tube (t) shows a cluster of jejunal loops (L) in the left upper quadrant. These loops are extrinsically compressed (*arrows*) at the entry site to the fossa of Landzert. (Courtesy Hans Herlinger, MD.)

A right paraduodenal hernia is a hernia of the jejunum into the mesentery of the ascending colon or right transverse mesocolon.⁴⁵ A right paraduodenal hernia occurs at the mesentericoparietal fossa (the fossa of Waldeyer), which is found in about 1% of autopsies.⁴⁷ This fossa lies in the upper portion of the jejunal mesentery, behind the superior mesenteric artery and just inferior to the third portion of the duodenum. The orifice of the hernia is bounded superiorly by the superior mesenteric artery and vein (small bowel mesentery). Once the proximal jejunum enters the orifice, it herniates to the right beneath the mesenteries of the transverse and/or ascending colon.

A right paraduodenal hernia may be manifested on barium studies by a variable number of jejunal loops clumped together in the right abdomen inferior to the third portion of the duodenum (Fig. 49-9). The herniated loops may be dilated and may show delayed emptying of barium. The inlet and outlet loops are closely apposed and narrowed because of extrinsic compression at the hernia orifice. CT or MRI may also reveal a focal cluster of jejunal loops in the right side of the abdomen inferior to the duodenum.⁴⁹ The branches of the superior mesenteric artery and vein are whirled posteriorly and to the right behind these vessels (Fig. 49-10), extending toward the right-sided jejunal loops.

Endometriosis

Endometrial tissue found outside the uterus is termed *endometriosis*. Diagnosis requires demonstration of at least two of the

following: glands, stroma, and hemosiderin related to bleeding.² This ectopic endometrial tissue primarily involves the peritoneal surfaces of the pelvis and pelvic organs, including the ovaries, fallopian tubes, and pouch of Douglas. Colonic involvement is found in 15% to 37% of women who undergo surgery for endometriosis.^{50,51} Ileal involvement is much less frequent,

Figure 49-9 Right paraduodenal hernia. This low-power spot image from a small bowel follow-through shows a large cluster of jejunal loops (J) clumped together in the right upper quadrant. Note how there is compression of one loop (arrow) at the inlet to the fossa of Waldeyer.

Figure 49-10 Right paraduodenal hernia. Axial CT through the tip of the liver shows collapsed bowel (S) in the right upper quadrant. A tributary (arrow) of the superior mesenteric vein is looping behind this vein (v). (From Herlinger H, Jones B, Jacobs JE: *Miscellaneous abnormalities of the small bowel*. In Gore RM, Levine MS [eds]: *Textbook of Gastrointestinal Radiology*. Philadelphia, WB Saunders, 2000, pp 865–883.)

found in only 1% to 7% of surgical cases.^{52,53} Ectopic endometrial tissue usually has a serosal or subserosal location, but endometrial tissue may burrow into the muscularis propria, submucosa, or even mucosa. The endometrial tissue goes through the proliferative and secretory phases of the menstrual cycle, with sloughing and bleeding, leading to regeneration of endometrial tissue and fibrosis.¹ Bowel involvement is primarily characterized by extensive subserosal fibrosis and serosal puckering. Endometrial tissue burrowing into the muscularis propria may result in increased muscle thickness. Small bowel involvement results in crampy abdominal or pelvic pain or symptoms of intestinal obstruction.^{54–57} Cyclic pain associated with menses is found in a minority (14%–40%) of patients.^{57,58}

Endometriosis may be manifested radiographically by findings similar to those found with intraperitoneal spread of malignant tumor or inflammatory diseases. Barium studies may reveal focal or multifocal areas of extrinsic mass effect on ileal loops associated with spiculation of the bowel contour and tethering of mucosal folds (Fig. 49-11).^{59,60} Circumferential narrowing may be present, but mucosal folds are preserved. The radiographic or CT findings can mimic those of intraperitoneal metastases to the bowel (Fig. 49-12) or of a carcinoid tumor with intraperitoneal spread. Rarely, a solitary deposit of ileal endometriosis can mimic a primary carcinoid tumor or appendicitis, secondarily involving the adjacent ileum.⁶⁰

Intestinal Edema

The small bowel has a limited number of ways to react to various insults. Bowel wall edema is one component of this reaction to a wide variety of inflammatory or ischemic

Figure 49-11 Ileal endometriosis. This spot image obtained during enteroclysis shows a focal, smooth, extrinsic mass impression (open arrows) on the mesenteric border of a pelvic loop of ileum. At a second site, there is another focal extrinsic mass impression (arrow) and tethering of folds toward the mesenteric border. The ileal mucosa is preserved. The distal ileum (i) is collapsed. These endometriosis implants in the ileum are indistinguishable from intraperitoneal metastases to the small bowel.

Figure 49-12 Ileal endometriosis. Axial CT through the pelvis shows ileal loops (long arrows) pulled toward the mesentery with associated tethering of folds (small arrow). The submucosa has slightly low attenuation.

conditions. This discussion focuses on bowel wall edema as the predominant component of this reaction.

Edema of the small intestine occurs primarily in the lamina propria and submucosa. This process is characterized by dilation of mucosal and submucosal lymphatics and increased interstitial fluid. Isolated bowel wall edema is usually associated with diseases that cause hypoalbuminemia (with a serum albumen level <2 g/dL).^{61,62} The two most common causes of small bowel edema are cirrhosis and the nephrotic syndrome. However, any intestinal disease associated with hypoalbuminemia related to malabsorption can cause bowel wall edema. For example, patients with gluten-sensitive enteropathy and hypoalbuminemia can have diffuse fold enlargement because of small bowel edema. Any intestinal disease that causes intraluminal protein loss can also result in hypoalbuminemia, including the enteropathy associated with congestive heart failure, constrictive pericarditis, and burns, Ménétrier's disease, lymphangiectasia, and Crohn's disease.^{61,63}

Several factors account for small bowel edema in patients with cirrhosis. Oncotic pressure is low as a result of hypoalbuminemia and hypovolemia. Small intestinal capillary pressure may also be elevated because of portal hypertension, congestive heart failure, and water and salt retention caused by decreased aldosterone catabolism and associated renal dysfunction.⁶¹⁻⁶⁴ In cirrhotics, congestive changes in the jejunum are similar to those of portal hypertensive gastropathy in the stomach, with an increased size and number of capillaries and venules in the lamina propria and submucosa.^{1,64}

Barium studies of the small bowel in patients with hypoalbuminemia may show smooth, straight, or slightly undulating, mildly thickened folds that are diffusely distributed throughout the small intestine (Fig. 49-13), although generally best visualized in the jejunum.⁶³ The luminal diameter of the jejunum is slightly increased.⁶² CT can also show edema of the small bowel

Figure 49-13 Small bowel edema in a patient with cirrhosis and hypoalbuminemia. This spot image from a small bowel follow-through shows diffusely thickened, smooth, straight folds (long arrows) perpendicular to the longitudinal axis of the bowel. Barium trapped between the folds forms the so-called interspace spikes (short arrows).

mesentery in 86% of patients. Omental and retroperitoneal edema is seen less frequently (56%).⁶⁵

Enteroliths and Bezoars

Bezoar derives from the Persian root *-padzahr*, meaning antidote.⁶⁶ A bezoar was a calculus found in the stomach or gallbladder of wild goats that lived in northeastern Persia. Bezoars were believed to have a variety of medicinal properties, especially as antidotes for poisoning. In humans, most bezoars are found in the stomach and are composed of indigestible organic substances such as hair (trichobezoars) or fruit (phytobezoars). Any vegetable or fruit with high fiber content can result in bezoar formation.

Bezoars and enteroliths are uncommon in the small intestine.⁶⁷ Bezoars form in areas of stasis such as the jejunal diverticula, Meckel's diverticulum, and bypassed small bowel loops after surgery for Crohn's disease. Bezoars also form proximally to strictures related to Crohn's disease, tuberculosis, or other causes. Small intestinal bezoars are composed of hair, undigested food, or medications such as nonabsorbable antacids. In areas of the world in which persimmons are eaten, most phytobezoars are related to the ingestion of unripe persimmons.^{68,69}

Small intestinal bezoars or enteroliths are intraluminal masses of mixed density and attenuation on CT (Fig. 49-14). These intraluminal masses may contain air, soft tissue, or calcium,^{70,71} and peripheral or laminated calcification may be present (see Fig. 49-14). Small intestinal bezoars are typically found in the distal ileum—the narrowest portion of the small bowel—or just proximal to pathologic areas of narrowing, such as strictures, anastomoses, or tumors. Bezoars can be confused with intraluminal gallstones associated with gallstone ileus. However, no air is identified in the biliary tree in patients with bezoars.

Figure 49-14 Enteroliths proximal to a stricture at the ileorectal anastomosis. A. Coned-down view from a plain abdominal radiograph shows three peripherally calcified ovoid structures (*large arrows*) near an anastomotic staple line (*small arrow*). **B.** Axial CT scan through the pelvis shows one of the enteroliths as a peripherally calcified structure (*large arrow*) containing central bubbles of air and soft tissue attenuation. Part of the staple line (*small arrows*) is identified.

The tables in this chapter (Tables 50-1 to 50-18) concerning the differential diagnosis of small bowel diseases are not meant to be exhaustive. Instead, these tables present an approach for classifying the most common causes of various radiographic abnormalities in the small bowel in relation to the size, location, distribution, and radiographic characteristics of these abnormalities. A list of references is included for further reading.¹⁻⁴⁰

Small Bowel Folds and Mucosal Changes

Small bowel villi are formed by a single-cell epithelial surface covering a lamina propria filled with fat, vessels, inflammatory cells, and a central lacteal. Fine nodularity of the mucosal surface (also termed *micronodularity* or a *sandlike pattern*) therefore reflects enlargement of villi, usually by an abnormality in the lamina propria, such as edema, inflammation, or infiltration by amyloid or other substances. Small bowel folds are composed of mucosa and submucosa. Enlarged or effaced small bowel folds therefore reflect edema, hemorrhage, inflammation, or tumor in the lamina propria and submucosa.

Tables 50-3 through 50-7 classify small intestinal diseases by their location in the small bowel and whether the folds are smoothly enlarged or are enlarged and nodular. Many diseases have abnormal villi and enlarged folds because the pathologic process involves the lamina propria and submucosa. Smooth fold thickening usually implies edema related to hypoalbuminemia or to edema or hemorrhage related to vascular causes. Nodular fold thickening implies inflammation or infiltration by tumor, amyloid, or other substances. It is often difficult to distinguish smooth fold enlargement from mildly nodular folds. The radiographic findings of diseases associated with edema or hemorrhage can therefore overlap with those of inflammatory and infiltrative diseases.

TABLE
50-1

Normal Small Bowel Parameters

Parameter	Jejunum	Ileum
NORMAL PARAMETERS FOR ENTEROCLYSIS		
Folds per inch length	4-7	2-4
Thickness of folds (mm)	1-2	1.0-1.5
Diameter of lumen (cm)	≤4	≤3
Wall thickness (mm)	1.0-1.5	1.0-1.5
NORMAL PARAMETERS FOR SMALL BOWEL FOLLOW-THROUGH		
Thickness of folds (mm)	2-3	1-2
Diameter of lumen (cm)	≤3	≤2

Data from references 1 and 2.

TABLE 50-2 Small Bowel Lumen Dilated, Normal Fold Thickness

Parameter	Cause	Comments
Diffuse small bowel dilation	Mechanical obstruction, small bowel or colon	Air-fluid levels on abdominal radiographs. CT if high grade obstruction suspected, barium studies for partial or intermittent obstruction Common causes—adhesions, hernias, metastases, radiation enteropathy, colonic carcinoma with backup into dilated small bowel
	Adynamic ileus	Air-fluid levels to distal small bowel and in colon Common causes—postoperative, medications, ischemia, vagotomy Less common causes—systemic sclerosis (dilated duodenum, hidebound small bowel), amyloidosis, peritonitis, electrolyte imbalances (hypokalemia, uremia), blunt trauma, diabetes, hypothyroidism
Focal small bowel dilation	Proximal obstruction	Fluid levels in few small bowel loops in upper abdomen—primary adenocarcinoma, postoperative strictures, adhesions
	Focal adynamic ileus	Pancreatitis, postoperative manipulation or leak, pelvic irradiation
	Closed-loop obstruction	Group of air-fluid levels unchanging in position CT for diagnosis and evaluation of possible strangulation
	Adhesions Internal hernia	Focal region of dilated loops with air-fluid levels

Data from references 1 to 5.

TABLE 50-3 Smooth, Straight, Thickened Folds

Parameter	Cause	Comments
Diffusely distributed	Edema	Hypoalbuminemia—cirrhosis, nephrotic syndrome Protein-losing enteropathy Congestive heart failure Portal hypertension
Focal smooth fold thickening	Intramural hemorrhage	Segmental stack of coins appearance; interspace spikes; thumbprinting on mesenteric border Most patients return to normal within 2-3 wk
	Ischemia	
	Anticoagulants	
	Coagulopathies	
	Superior mesenteric vein thrombosis	
	Vasculitides	Ischemic changes, hemorrhage, ulceration or necrosis with small vessel disease (lupus, Henoch-Schönlein purpura)
	Blunt trauma	CT—look for possible perforation (e.g., mesenteric haziness or fluid, thickened bowel wall, lack of bowel contrast enhancement, focal pneumatosis, free intraperitoneal gas)
	Radiation enteropathy	Thickened folds, narrow interfold spaces (interspace spikes); barium changes resemble picket fence Changes confined to radiation portal

Data from references 1, 6 to 10, and 40.

TABLE 50-4 Micronodularity

Cause	Comments
Whipple's disease	White males with arthralgias, cardiovascular and neurologic symptoms CT—low-attenuation mesenteric lymph node mass
<i>Mycobacterium avium-intracellulare</i> (MAI) complex enteritis	AIDS MAI-laden macrophages in lamina propria CT—shows necrosis in enlarged lymph nodes
Abetalipoproteinemia	Adolescent with retinitis pigmentosa, acanthocytosis, spinocerebellar degeneration Retained fat globules in villous enterocytes
Histoplasmosis	<i>Histoplasma</i> -laden macrophages in lamina propria
Lymphangiectasia	Villi enlarged by dilated lacteals in primary form Edema in submucosa Mesenteric adenopathy causes secondary form
Macroglobulinemia	Lymphoma—may occur IgM macroglobulin in lamina propria
Radiation therapy	Associated with smooth, thickened, straight folds
Crohn's disease	Distal, terminal ileum Aphthoid ulcers, mesenteric border ulcers; cobblestoning; strictures, fissures, fistulae

*1- to 2-mm mucosal nodules. Micronodularity implies villous enlargement caused by an infiltrative process in lamina propria. This table lists diseases that often involve the mucosa and submucosa and also produce abnormal folds.

Data from references 1 to 9 and 11 to 16.

TABLE 50-5 Irregular Fold Thickening, Diffuse

Cause	Comments
Lymphangiectasia, primary	Submucosal edema plus micronodularity Congenital hypoplasia of lymphatics
Lymphangiectasia, secondary	Small bowel changes (as above) Obstruction of lymph drainage by retroperitoneal fibrosis, radiation, mesenteric lymphadenopathy (Whipple's, lymphoma)
Amyloidosis, types AA and AL	Fold thickening if deposits in vessels cause ischemia. Micronodularity in secondary amyloidosis—reflects amyloid deposits in lamina propria
Mastocytosis	4- to 10-mm nodules in submucosa (AL) Histamine release—associated headaches, flushing, diarrhea; urticaria pigmentosa (50%), bone lesions (20%) Stomach, duodenum—ulcers Small bowel—multiple urticaria-like nodules Thickened folds often segmental
Immunoproliferative small intestinal disease (IPSID)	Relates to multiple parasitic and/or bacterial infections Patient from Mediterranean region Extensive lymphoid hyperplasia Responds to treatment
Mediterranean lymphoma	Young patient with progression of IPSID to monoclonal lymphomatous infiltrate Lymphoid nodules enlarged, nonuniform, confluent Lymph node masses
AIDS	Associated with a heavy-chain disease
Graft-versus-host disease	Large variety of infections cause diffuse thickened folds. Often with cytomegalovirus infection (see Table 50-8)

Data from references 1 and 15 to 17.

TABLE 50-6 Irregular Fold Thickening, Proximal Small Bowel

Cause	Comments
T-cell lymphoma complicating celiac disease	Diarrhea recurs despite gluten-free diet Nodular fold thickening in long segments May have annular lesions
Ulcerative jejunoileitis	Complicates celiac disease Before inflammatory infiltrate changes to monoclonal lymphoma Radiographically indistinguishable from T-cell lymphoma
Tropical sprue	History of sojourn in tropics Unlike celiac disease, folds are thickened, no separation of jejunal folds
Zollinger-Ellison syndrome	Gastric and duodenal ulcers Increased intraluminal fluid
Strongyloidiasis	Effaced folds, tubular bowel contour with severe disease
AIDS-related infections	<i>Mycobacterium avium-intracellulare</i> (MAI) complex, isosporiasis, cryptosporidiosis
Gastrojejunostomy	Thick folds in efferent loop just distal to gastrojejunal anastomosis
Jejunostomy tube	Reaction to tube feeds

Data from references 1, 2, 5, and 18.

TABLE 50-7 Irregular Fold Thickening, Distal Ileum

Parameter	Cause	Comments
Minimal luminal narrowing	Crohn's disease, early	Coarse villous pattern, aphthoid ulcers Uncommon pattern if no associated colonic disease Not an unusual pattern in neoterminal ileum
	<i>Yersinia</i> enterocolitis	Early—thickened, nodular folds, ulcers 5-8 wk—lymphoid hyperplasia 8-12 wk—normal terminal ileum
	Salmonellosis, campylobacteriosis Mantle cell lymphoma	Similar to <i>Yersinia</i> but more ulceration Part of systemic disease Multiple nodules, mesenteric masses Prognosis poor
Moderate to marked luminal narrowing	Crohn's disease	Narrowing may change in diameter if caused by spasm, edema, or inflammation rather than fibrosis Mild—mesenteric border ulceration and antimesenteric sacculation Moderate—transmural extension with luminal narrowing and ulceronodular pattern Severe—strictures, fissures, fistulae CT best to determine presence of mesenteric abscesses
	Tuberculosis	Patient from endemic area or immunodeficient More pronounced in cecum, right colon Ulcers, transverse folds, patulous ileocecal valve, retracted cecum May be indistinguishable from Crohn's disease
	Behçet's disease	Associated with uveitis, genital ulcers, arthritis Penetrating ulcers, especially in colon
	AIDS-related infections	Cytomegalovirus, actinomycosis
	Cecal carcinoma, lymphoma	Cecal mass associated with retrograde extension of tumor via lymphatics into terminal ileum Thickened nodular folds

Data from references 1 and 19 to 24.

TABLE 50-8 Tubular Bowel with Luminal Narrowing

Cause	Comments
Graft-versus-host disease	Often complicated by cytomegalovirus infection Diffuse small bowel involvement "Toothpaste" appearance is function of rapid transit
Chronic ischemic changes	Prolonged adherence of barium Radiation or amyloidosis
Burnt-out Crohn's disease	Hypoperistaltic or aperistaltic loops Distal ileum
Strongyloidiasis	Active disease may be present nearby Jejunum Severe disease, but reversible

Data from references 1, 7, 10, 16, 17, 24, and 25.

TABLE 50-9 Tubular Bowel without Luminal Narrowing

Cause	Comments
Primary lymphoma	Segmental infiltrate effaces fold pattern 5-15 cm in length
Celiac disease, long-standing	Near-absence of folds in proximal jejunum Associated with a mosaic pattern

Data from references 1 to 3, 5, and 18.

TABLE 50-10 Solitary Polyp

Cause	Comments
Carcinoid, early	80% of carcinoid tumors in distal ileum Polyp in ileum—exclude carcinoid 30% multiple Early form of tumor (0.5-2.0 cm) before invasion and desmoplastic effect
Lipoma	Elongated lesions with pseudopedicle May ulcerate, change in shape CT—fat attenuation
Adenoma	85% of adenomas in duodenum 10% of adenomas in jejunum
Brunner gland polyp	First or second portions of duodenum
Hemangioma	Sessile polyp or carpet lesion May contain phleboliths
Gastrointestinal stromal tumor	Sessile polyp or target lesion Cavitary mass when large
Neurofibroma	Association with neurofibromatosis
Gangliocytic paraganglioma	Near papilla of Vater
Inverted Meckel's diverticulum	Elongated intraluminal "polyp" in distal ileum Associated with intussusception
Inflammatory fibroid polyp	Usually in ileum Elongated polyp composed of granulation tissue, with eosinophils

Data from references 1 and 26 to 28.

TABLE 50-11 Multiple Polyps and Polyposis Syndromes

Parameter	Cause	Comments
Multiple polyps	Hematogenous metastases	Most commonly metastatic melanoma
	Kaposi's sarcoma	Submucosal mass Known AIDS Plaque, submucosal mass, or target lesion
Polyposis syndromes	Carcinoid tumor	Multiple in 30% (see Table 50-10)
	Disseminated lymphoma	Multiple submucosal masses or target lesions
	Mantle cell lymphoma	Lymphomatous polyposis
	Peutz-Jeghers syndrome	Autosomal dominant, but 40% of patients are spontaneous mutants Sessile or pedunculated polyp with lobulated or villous surface Jejunum Young patients with bleeding or pain; pigmented lesions on mouth, lips, palms
	Cowden's disease	Autosomal dominant Polyps of varying histologies but hamartomatous polyps more often in colon than in small bowel Facial papillomas Associated thyroid disease (66%) and breast carcinoma (33%-50%)
	Cronkhite-Canada syndrome	Nonhereditary; mean age of 60 yr Diarrhea, ectodermal changes, protein loss Inflammatory polyps more frequent in stomach and in colon than in duodenum or small bowel
	Familial adenomatous polyposis syndrome	Autosomal dominant; 10%-30% of patients are spontaneous mutants Mutations in various portions of APC gene produce various clinical syndromes (e.g., Gardner's, Turcot's) Small bowel adenomas primarily in duodenum 12% develop periampullary carcinomas Desmoid tumors in root of small bowel mesentery
	Neurofibromatosis	Known clinical diagnosis

Data from reference 1.

TABLE 50-12 Multiple Target Lesions

Cause	Comments
Melanoma metastases	Hematogenous spread Submucosal lesions, often on antimesenteric border Large ulcer with spoke wheel radiating folds
Other hematogenous metastases	Breast and lung cancer
Lymphoma, disseminated	Involves stomach more frequently than small bowel
Kaposi's sarcoma	Involves stomach and duodenum more frequently than small bowel Plaquelike lesion or thickened folds more common morphologic forms Homosexuals with AIDS

Data from references 1 and 13.

TABLE 50-13 Annular Lesion with Shelflike Margins

Cause	Comments
Small bowel obstruction by adhesive band	Transition zone with sharply demarcated band compressing against distended proximal and collapsed distal small bowel Shelflike or beaklike narrowing Adjacent folds are normal; no mucosal nodularity
Adenocarcinoma, primary	Proximal jejunum Short lesion with shouldering Central ulceration; folds destroyed or nodular Obstruction not severe, unless late diagnosis
Metastases	Colon cancer most frequent primary tumor Mid to distal small bowel Desmoplasia with angulation causing obstruction Folds relatively preserved but may be tethered
Primary small bowel lymphoma	Long lesion without obstruction Nodular folds and effaced mucosa Center bulges aneurysmally Multiple in up to 25% of patients
Carcinoid	Misleading en face appearance of saddle lesion (polypoid lesion spreading circumferentially)
Anastomotic stricture	Clinical history; staple line
NSAID stricture	Multiple, ringlike thickened webs causing low-grade obstruction

Data from references 1, 18, and 29 to 35.

TABLE 50-14 Annular Lesion with Tapered Edges

Cause	Comments
Adhesion	Beaklike tapering with smooth folds
Crohn's disease	Stricture caused by primary disease or skip lesion Associated cobblestoning or mesenteric border ulcers
Radiation enteropathy	Strictures within area of severe damage or at entry site into radiation field Bowel loops often angulated; folds tethered because of serositis or fibrosis
Ischemia	Usually low-grade obstruction May be related to trauma

Data from references 1, 10, 23, and 24.

TABLE 50-15 Exoenteric Cavitary Lesions

Parameter	Comments
COMMON CAUSES	
Primary non-Hodgkin's lymphoma	Transmural ulceration with perforation into mesentery or cavitation of tumor that has invaded mesentery
Metastatic melanoma	Large, deeply ulcerated metastases
Malignant gastrointestinal stromal tumor	Cavity caused by central necrosis in tumor that subsequently communicates with bowel lumen or by ischemic necrosis of epithelium overlying tumor, with secondary ulceration
UNCOMMON CAUSES	
Adenocarcinoma	Deeply ulcerated tumor perforates
Jejunal diverticulitis with abscess cavity	
Ectopic pancreas with pancreatitis and pseudocyst formation	
Hematogenous metastasis from pulmonary carcinoma	
Crohn's disease	Fistula or perforation forms abscess cavity Other findings of Crohn's disease

Data from references 1, 13, 18, 37, and 38.

TABLE 50-16 Separation of Bowel Loops without Tethering

Cause	Comments
Prominent fat within small bowel mesentery	Most common of cause of separated loops More pronounced in ileum
Ascites	Loops retain normal pliability and mobility Small bowel loops centrally located CT for cause
Mesenteric masses	Lymphoma of mesenteric nodal origin — enlarges and displaces bowel; may surround it without obstruction (sandwich sign); later infiltrates intestinal wall causing obstruction Desmoid tumor related to familial adenomatous polyposis syndrome
Crohn's disease	CT distinguishes bunching of fat caused by mesenteric inflammation and scarring (fibrofatty proliferation) from abscess

Data from references 1 and 18.

TABLE 50-17 Mass Effect with Tethering of Mucosal Folds

Causes	Comments
Intraperitoneal metastases	Right lower quadrant, pelvis Multiple hemispheric masses on mesenteric border of distal ileum with crowded, tethered folds
Carcinoid tumor, early	Hemispheric sessile polyp, with adjacent desmoplastic crowding of folds Multiple in 30%
Carcinoid tumor, advanced	Intense desmoplastic effect on adjacent bowel loops Mesenteric metastases grow larger than primary tumor CT—central mesenteric mass (calcified in 50%), mesenteric stranding Associated with ascites, small bowel ischemia
Interloop or omental abscess	Extrinsic mass with mildly edematous folds radiating toward abscess
Retractile mesenteritis	Intestinal loops separated and pulled toward mesentery CT shows soft tissue mesenteric masses
Endometriosis	Sharply demarcated plaques invade serosa causing pleating of underlying mucosa Pelvic and terminal ileum; more often involves rectosigmoid colon
Pancreatitis	Desmoplastic changes in left upper quadrant: jejunum and splenic flexure
Root of mesentery nodal metastasis	At or left of duodenojejunal junction—left-sided colon cancer, transitional cell carcinoma of bladder Near second portion of duodenum—right-sided colon cancer
Cecal or appendiceal process involving terminal ileum	Cecal lymphoma, carcinoma Appendicitis Appendiceal tumors
Crohn's disease	Abscess, inflammatory process in mesentery Other findings of Crohn's disease

Data from references 1 and 38.

TABLE 50-18 Site Predilection of Diseases

Site	Disease
Proximal jejunum	Adenocarcinoma Jejunal diverticulosis Infections: giardiasis, Whipple's disease, cryptosporidiosis, isosporiasis Celiac disease Zollinger-Ellison–related pathology Polyps in Peutz-Jeghers syndrome
Distal ileum	Crohn's disease Carcinoid tumors Ileitis caused by <i>Yersinia</i> , <i>Campylobacter</i> , cytomegalovirus, Behçet's disease Intraperitoneal metastases Secondary involvement by inflammatory or neoplastic disease of cecum or appendix
Antimesenteric border	Radiation enteropathy Tuberculosis (right-sided colonic predominance) Meckel's diverticulum Hematogenous metastases
Mesenteric border	Sacculation in Crohn's disease Linear ulcers in Crohn's disease Peritoneally seeded metastases Jejunal diverticula Thumbprinting caused by intramural bleeding Mesenteric hematoma Intestinal duplication Cavitation in primary intestinal lymphoma

Data from references 1 to 5, 9 to 11, 13, 18, 21 to 24, 30, 39, and 40.

Single- Versus Double-Contrast Technique

Double-Contrast Barium Enema

Preparation of the Patient

Materials and Equipment

Single-Contrast Barium Enema

Technical Problems

Poor Preparation

Diverticulosis

Incontinence

Filling of Entire Colon

Complications

Variations in Technique

Suspected Perforation

Peroral Pneumocolon

Colostomy Enema

The overall volume of barium enemas has decreased considerably in modern medical practice because of greater use of other diagnostic tests such as colonoscopy, computed tomography (CT) and, most recently, CT colonography. Nevertheless, the barium enema remains a valuable technique for evaluating patients with a variety of colorectal diseases. The double-contrast barium enema, in particular, has been shown to be a viable alternative to colonoscopy for colorectal cancer screening¹ and for detecting polyps and cancers in the proximal colon in patients with incomplete colonoscopy.² Both single- and double-contrast barium enemas also have the ability to demonstrate a variety of intramural and extrinsic abnormalities involving the colon that are more difficult to recognize at colonoscopy. In such cases, the full extent of disease may then be assessed by cross-sectional imaging studies such as CT.

Depending on the clinical indications for the barium enema and the patient's overall condition, single- or double-contrast techniques may be used to evaluate the colon. We believe that a double-contrast barium enema is generally the preferred examination because of its greater diagnostic capabilities, so it has received more emphasis in this chapter.

Single- Versus Double-Contrast Technique

Double-contrast technique is generally thought to be superior to single-contrast technique for detecting small polypoid lesions or flat carpet lesions (villous tumors) in the colon and for visualizing the early inflammatory changes of inflammatory

bowel disease (Crohn's disease and ulcerative colitis).^{3,4} This advantage of double-contrast technique is related to its ability to visualize the mucosal surface en face on double-contrast images. There are also specific signs such as the mucosal spiculation of endometriosis or metastatic disease that are better demonstrated on double-contrast studies (see Chapter 3).^{5,6} Finally, double-contrast technique enables evaluation of the rectum, which is not accessible to manual palpation on single-contrast studies.⁷

In contrast, single-contrast technique entails filling of each colonic loop with a continuous column of barium, enabling visualization of contour abnormalities such as polyps or ulcers in profile and circumferential areas of narrowing such as annular carcinomas. Polyps and polypoid masses can also be visualized en face by thinning the barium column with graded compression to delineate these lesions as filling defects within the barium pool. Despite the limitations of single-contrast technique in detecting polyps, it is the preferred examination for patients with suspected fistulas, obstruction, or intussusception, in whom careful control of the barium column is required. Single-contrast technique is also useful for showing ischemic colitis associated with thumbprinting that can be effaced by gaseous distention of the colon on double-contrast studies.⁸ Finally, single-contrast technique is used for patients who are too old or too debilitated to perform the various maneuvers required for a double-contrast study or in patients with poor sphincter tone who may be unable to retain rectally administered air, even with inflation of a rectal balloon.

Double-Contrast Barium Enema

PREPARATION OF THE PATIENT

A variety of regimens may be used for cleansing the colon, but most include the following basic components⁹:

- A clear liquid diet for 24 hours
- One or preferably two sets of laxatives on the afternoon and evening before the examination (e.g., one 16-ounce bottle of magnesium sulfate at 4 PM and four Dulcolax [bisacodyl] tablets at 10 PM)
- A suppository (e.g., a Dulcolax suppository) on the morning of the examination

If followed properly, this basic preparation is usually effective in cleansing the colon, but noncompliance can be a problem. When patients arrive in the department, they should be asked whether they have taken the preparation and whether it has been effective in producing clear, watery bowel movements. If there is any doubt about the adequacy of the preparation, a preliminary abdominal radiograph should be obtained. If this radiograph shows definite fecal residue in the colon, the examination should be postponed for 24 hours while the patient repeats the preparation.

Cleansing enemas may improve the cleanliness of the colon but are not generally recommended because residual fluid in the colon may dilute administered barium and limit mucosal coating, compromising the examination. For similar reasons, oral lavage regimens with solutions used to prepare patients for colonoscopy, such as GoLYTELY (polyethylene glycol electrolyte solution), should be avoided.¹⁰

MATERIALS AND EQUIPMENT

The choice of barium suspension is critical. A medium barium suspension of approximately 100% w/v is generally preferred for double-contrast barium enemas. Barium of this viscosity optimally coats the mucosa for a relatively prolonged period without precipitating or causing other artifacts. A Miller air enema tip is ideal for instilling barium and air into the colon.¹¹ The retention balloon attached to the enema tip is inflated only if the patient is unable to retain the barium or air because of inadequate anal sphincter tone (see later, “Insertion of Enema Tip”).

In modern radiology departments, barium enema examinations are almost always performed on digital fluoroscopic equipment. For double-contrast studies, the radiologist relies on fluoroscopy to position the patient for a series of digital spot images, followed by a routine sequence of overhead radiographs (see next section, “Routine Examination”).¹² Careful evaluation of the frozen image on the fluoroscopic monitor after each digital exposure enables the radiologist to better delineate subtle colonic abnormalities and differentiate spurious findings from true lesions at the time of fluoroscopy. The study is later reviewed at a computer workstation that allows routine postprocessing of the images for optimal interpretation.¹³ Subtle mucosal abnormalities and differences in density (e.g., as in patients with pneumatosis coli) may be apparent only after adjustment of the images.¹⁴

Administration of Glucagon

A standard dose of 1 mg of glucagon should be administered intravenously to improve the quality of the examination and decrease patient discomfort by producing a relaxant effect on the colon and eliminating or minimizing colonic spasm.^{15,16} The glucagon should be injected slowly to avoid nausea and vomiting, a frequent but transient side effect. Glucagon can be given to almost all patients, but this agent is contraindicated in patients with pheochromocytomas or poorly controlled, insulin-dependent diabetes.

Insertion of Enema Tip

Before inserting the lubricated enema tip, a brief digital rectal examination should be performed to assess anal sphincter tone and recognize anatomic variations that could interfere with insertion of the tip. In patients with an enlarged prostate, for example, the enema tip should be directed more posteriorly than usual to facilitate passage into the rectum. In patients with large external hemorrhoids or anal fissures, a topical anesthetic may be applied to the anus and enema tip to minimize discomfort during insertion. Patients who experience unusual discomfort when the tip is inserted should be reassured that the rectum quickly accommodates to the tip, so any discomfort they experience will be transient.

Routine Examination

A routine series of fluoroscopic spot images for double-contrast barium enemas is presented in Table 51-1, and selected views are illustrated in Figure 51-1. When the fluoroscopic portion of the study has been completed, a standard sequence of overhead radiographs is also obtained (see Fig. 51-1 and Table 51-1). The overhead radiographs include horizontal beam views—left and right lateral decubitus radiographs and a prone cross-table lateral radiograph—that are especially useful for differentiating retained stool from true polypoid lesions in the colon (Fig. 51-2).

Barium is usually administered into the colon under fluoroscopic guidance with the patient in a prone or left lateral position to facilitate passage of barium into the dependent sigmoid and descending colon. It is important to be certain that barium has passed around the splenic flexure into the transverse colon before draining barium and insufflating air because it can be difficult to propel the barium into the ascending colon and cecum if not enough barium has been administered. This problem is more likely to occur in patients with a long, redundant, barium-filled sigmoid colon extending into the left upper quadrant that is inadvertently mistaken for the splenic flexure (see later, “Filling of Entire Colon”).

As soon as enough air has been insufflated to distend the colon, double-contrast spot images should be obtained, starting with the sigmoid colon and continuing proximally in a systematic fashion. Early imaging of the sigmoid colon is particularly important because this portion of the colon may be obscured by opacified small bowel if barium refluxes via an incompetent ileocecal valve into pelvic loops of ileum. After all the loops in the sigmoid colon have been visualized with appropriate spot images, additional images of looping segments of the descending, transverse, and ascending colon should also be obtained. The patient should be rotated as needed under fluoroscopic guidance to visualize individual loops of colon in double contrast and avoid overlap with other loops, which could obscure polypoid or even annular lesions. With careful technique and attention to detail, even small subtle polyps can be detected.

As the patient turns, it is useful to watch the flow of barium across the mucosal surface because flow technique can be extremely helpful for delineating flat protruded lesions, shallow ulcerated lesions, and other subtle abnormalities in the colon. If a particular loop of colon is filled with barium because of its dependent location when the patient is in a supine position, she

TABLE 51-1 Routine Double-Contrast Barium Enema	
Position	Views
SPOT RADIOGRAPHS	
Prone	Rectum
Left posterior oblique	Sigmoid colon
Left lateral	Rectum
Supine	Rectum and cecum
Upright	Hepatic and splenic flexures
Supine, supine obliques	All remaining colonic segments
OVERHEAD RADIOGRAPHS	
Vertical beam	Posteroanterior
Angled (prone)	Rectosigmoid
Horizontal beam	Left and right lateral decubitus views
	Prone cross-table lateral view

or he should be turned into a prone position to visualize the same loop in double contrast by placing it in a nondependent location. Routine upright positioning of the patient is also important for obtaining optimal double-contrast views of the hepatic and splenic flexures. In patients with inguinal hernias, upright views may also be helpful for showing one or more loops of sigmoid colon or distal ileum within the hernias.

When the table is returned to a recumbent position, barium in the hepatic flexure falls by gravity into the ascending colon and cecum, so spot images of the cecum can be obtained. If too much barium is present in the cecum to visualize this structure adequately in double contrast, the patient should be slowly

rotated into a steep right posterior oblique or right lateral position, causing barium to flow from the cecum along the right lateral wall of the ascending colon toward the hepatic flexure and, simultaneously, air to rise into the cecum. The patient can then be returned to a supine position for adequate double-contrast views of the cecum.

Because the enema tip itself may obscure lesions in the distal rectum, the tip should be removed before obtaining spot images of this structure. The patient is usually placed in a left lateral position and asked to bear down to drain barium from the rectum before insufflating additional air to redistend the rectum. After the tip has been removed, spot images of the

Figure 51-1 Selected radiographs from normal examinations. **A.** Spot radiograph of the sigmoid colon in the left posterior oblique position. **B.** Upright spot radiograph of the splenic flexure in the right posterior oblique position. **C.** Spot radiograph of the cecum and terminal ileum in the supine position. **D.** Overhead radiograph in the prone position.

(**B** and **D** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 51-2 Importance of the decubitus view with imperfect bowel preparation. **A.** Oblique view shows considerable fecal residue in the right colon. **B.** Left lateral decubitus overhead radiograph shows fecal debris layering out in the barium, enabling a clear view of most of the right colon.

rectum are routinely obtained with the patient in left lateral, prone, and supine positions, respectively, to complete the fluoroscopic examination.

If barium accumulates in the rectum during the procedure, some patients may experience discomfort as they resist the natural urge to expel this barium from the rectum. Such

discomfort can be avoided by checking the rectum periodically at fluoroscopy and, if necessary, dropping the enema bag to the floor and having the patient gently bear down to eliminate excess barium from the rectum.

The digital spot images should be carefully reviewed at the control station adjoining the fluoroscopy room while the

overhead radiographs are being taken. Any questionable abnormalities should prompt further evaluation of the colon under fluoroscopic guidance after the overheads have been obtained to eliminate uncertainty and permit a more definitive radiologic diagnosis. When the examination has been completed, the patient should be granted immediate access to a conveniently located bathroom to evacuate administered barium and air from the colon.

Normal Appearances

The mucosal surface of the colon usually has a smooth, featureless appearance (Fig. 51-3A). In some patients, a fine network,

also known as innominate grooves or lines, may be seen on the mucosa (Fig. 51-3B).¹⁷ These grooves can be visualized en face with double-contrast technique or in profile in the barium-filled colon when it is partially collapsed (Fig. 51-3C).¹⁸ Occasionally, double-contrast views may reveal innominate pits rather than grooves (Fig. 51-3D).¹⁹ This normal finding should not be mistaken for superficial ulceration. In other patients, transverse striations are observed as a transient phenomenon caused by contraction of the muscularis mucosae (Fig. 51-3E). Still other patients have tiny (1- to 3-mm) nodules in the colon caused by prominent lymphoid follicles, which are observed most often in children but can also be seen as a normal finding

Figure 51-3 Normal mucosal surface. **A.** The smooth, featureless surface of the colon usually seen on double-contrast studies. **B.** Innominate grooves on the surface of the colon. **C.** Single-contrast view shows the profile appearance of the innominate lines. **D.** Surface pattern in a normal adult showing pinpoint barium collections (innominate pits) both en face and in profile. These tiny pits should not be mistaken for ulcers. **E.** Transient striations in the transverse colon caused by contraction of the muscularis mucosae. There are also punctate barium collections representing tiny diverticula (arrow). (B from Laufer I: *Double Contrast Gastrointestinal Radiology with Endoscopic Correlation*. Philadelphia, WB Saunders, 1979; C and D from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

Figure 51-4 Lymphoid follicular pattern. **A.** Tiny rounded filling defects in the transverse colon constitute the normal lymphoid follicular pattern. **B.** Prominent lymphoid follicular pattern in another patient with a small polypoid colonic carcinoma (arrow). **C.** Normal lymphoid follicles in the terminal ileum.

in adults (Fig. 51-4A).^{20,21} Enlarged lymphoid follicles may be associated with a variety of conditions, including Crohn's disease, lymphoma, and immune deficiency states.²² Unusually prominent lymphoid follicles have also been reported in patients with colonic carcinoma (Fig. 51-4B),²³ so this observation should prompt a careful search for underlying malignant tumors in the colon. Enlarged lymphoid follicles may also be seen as a normal finding in the terminal ileum in young people (Fig. 51-4C) and in patients with conditions such as *Yersinia* enteritis and lymphoma.

Single-Contrast Barium Enema

Single-contrast barium enemas entail filling the entire colon with a solid column of barium of relatively low viscosity. Patient preparation, administration of glucagon, and insertion of the enema tip are the same as for double-contrast barium enemas (see earlier). Barium is usually introduced with the patient in a left lateral position. For patients with decreased or absent anal sphincter tone, the retention balloon on the enema tip should be inflated to facilitate retention of barium (see later, "Incontinence").

After the rectum has been evaluated, and as the remaining colon is filled with barium, the patient should be turned from the left lateral position into supine and supine oblique positions, and digital spot images of each colonic loop and flexure should be obtained. The patient should be rotated into different degrees of obliquity as needed to avoid or minimize overlapping bowel. The examination is not completed until the entire colon, including the cecum, has been visualized.

A critical component of the single-contrast enema is graded manual compression of the colon under fluoroscopic guidance to thin out the administered barium and visualize protruded lesions (e.g., polyps and polypoid carcinomas) en face as filling defects in the barium pool. Manual compression may be applied

with a leaded glove, balsam paddle, or the compression cone on the fluoroscopy tower. The ability to demonstrate polyps (especially small polyps) with graded compression requires some skill because these lesions can be missed if the colon is under-compressed or overcompressed at fluoroscopy. With practice and experience, even subtle protruded lesions can be visualized. Nevertheless, the hepatic and splenic flexures and rectum are often difficult to evaluate because of overlying bony structures (the rib cage and pelvic bones) that preclude manual palpation of these areas.

The single-contrast barium enema relies primarily on fluoroscopic evaluation of the colon (with appropriate spot images) to demonstrate abnormalities in the colon, so overhead radiographs are not routinely obtained. However, postevacuation radiographs may be helpful for showing protruded lesions on mucosal relief views of the collapsed colon. Postevacuation radiographs are also useful for assessing colonic emptying in patients with possible colonic motility disorders.

Technical Problems

POOR PREPARATION

Poor colonic preparation is a major limiting factor with barium enemas because of difficulty detecting polypoid lesions in the presence of retained stool. Poor preparation can also simulate pathologic conditions such as inflammatory bowel disease (Fig. 51-5). Similarly, retained fecal debris can mimic the appearance of polypoid tumors. Nevertheless, fecal debris can be differentiated from true polypoid lesions on double-contrast studies when retained stool falls into the barium pool on horizontal beam radiographs because of the effect of gravity. In general, fecal debris will be seen on the dependent surface, whereas true polypoid lesions on the nondependent surface will be etched in white (Fig. 51-6; see Chapter 2).

Figure 51-5 Poor preparation simulating inflammatory bowel disease. **A.** Initial study suggests that the mucosa is abnormal throughout the colon. **B.** Another examination with adequate colonic preparation shows that the mucosal surface is normal.

Figure 51-6 Detection of a polyp despite fecal debris. **A.** There is considerable fecal debris in the left side of the colon. Nevertheless, a polyp can be recognized as a lesion that is etched in white (arrow). **B.** After the fecal material has been cleared away, a repeat spot radiograph shows the pedunculated polyp (arrow) more clearly.

DIVERTICULOSIS

The presence of marked sigmoid diverticulosis poses a serious diagnostic dilemma for detecting polypoid lesions on double-contrast barium enemas because of frequent difficulty detecting protruded lesions in the presence of numerous diverticula. When filled with air, these diverticula may simulate polyps on the nondependent surface. In such cases, the sigmoid colon may be reexamined by single-contrast technique (also known as a sigmoid flush) to better visualize protruded lesions (Fig. 51-7).²⁴ Alternatively, sigmoidoscopy may be performed to exclude neoplastic lesions in the sigmoid colon more confidently.

INCONTINENCE

Incontinence is another factor that may preclude performing a complete or technically adequate single- or double-contrast barium enema examination. When patients are incontinent

because of decreased or absent anal sphincter tone, the retention balloon on the enema tip may be inflated with air to prevent loss of barium from the rectum. Although inflation of the balloon often salvages the study in incontinent individuals, it places the patient at risk for rectal perforation. The best way to minimize that risk is to follow basic guidelines for inflating the balloon.

Most importantly, the retention balloon should be inflated only in patients in whom a diagnostic barium enema otherwise would not be possible because of inadequate anal sphincter tone. Before the balloon is inflated, a careful history should be obtained for any risk factors for rectal perforation (including rectal neoplasms, severe proctitis, pelvic irradiation, and rectal surgery) because these are contraindications for inflating the balloon. If no such risk factors are present, barium should be administered into the rectum under fluoroscopic guidance before inflating the balloon. If the rectum distends normally, the retention balloon should be inflated with no more than

Figure 51-7 Diverticulosis with sigmoid flush. **A.** The diverticula are obvious on the double-contrast study, but a polypoid cancer cannot be identified. **B.** After refilling the colon with single-contrast barium, a polypoid cancer (arrow) is seen. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 2nd ed. Philadelphia, WB Saunders, 1992.)

100 mL of air by the radiologist (not the technologist) under fluoroscopic guidance to be certain that the balloon does not encounter resistance and is not overinflated. The balloon should be retracted distally against the anal verge to produce a tight seal, which prevents leakage of barium or air from the rectum during the examination.

FILLING OF ENTIRE COLON

Unless there is an obstructing lesion, the colon should be filled in its entirety from the rectum to the cecum. The fluoroscopist can be certain the cecum has filled when there is reflux of barium into the terminal ileum or appendix. Even in the absence of reflux into these structures, one can be confident of cecal filling when the ileocecal valve is identified. It is occasionally difficult to fill the right side of the colon on double-contrast barium enemas in patients with an unusually tortuous or redundant colon or in patients with a mobile, anteriorly rotated cecum caused by embryologic absence of fixation of the ascending colon in the right paracolic gutter. In such cases, an incompletely filled ascending colon should not be mistaken for the cecum, and the patient should be rotated additional times, as needed, until the cecum is definitively visualized. Rarely, it may be necessary to convert a double-contrast barium enema to a single-contrast study to obtain adequate filling of the ascending colon and cecum in patients with glucagon-resistant spasm.²⁵

Complications

Some patients experience abdominal discomfort or gas pains during and after barium enema examinations.²⁶ This discomfort can be minimized by using carbon dioxide instead of air to distend the colon.²⁷ The most serious complication is colonic perforation.²⁸ Although extremely uncommon, the usual site of perforation is the rectum; most cases result from inflation of a rectal balloon in a diseased rectum (see earlier, “*Incontinence*”). When rectal injury occurs, barium may be seen dissecting into the wall of the rectum (Fig. 51-8A) or extravasating into the pelvis or retroperitoneum. Much less frequently, there is

perforation of the intraperitoneal portion of the colon, almost always at the site of diseased bowel, with barium entering the peritoneal cavity (Fig. 51-8B). In patients with diverticulosis, administered air may extravasate from the diverticula during the double-contrast barium enema, resulting in the development of retroperitoneal or intraperitoneal air, or even pneumomediastinum (Fig. 51-8C).

A barium enema examination should not be performed immediately after endoscopic biopsy of normal or inflamed rectal mucosa with a large biopsy forceps because such patients are at risk for rectal perforation.^{29,30} If a deep rectal biopsy specimen has been obtained, the barium enema should therefore be postponed for at least 5 days. In contrast, more superficial biopsies performed with a small forceps through flexible endoscopes need not necessitate such lengthy delays.

Allergic complications are rare, but have been reported.³¹ Such patients may have reactions to the barium itself or to various additives, latex rectal catheters, or even glucagon. Latex enema tips have been replaced by silicone tips because the latex was thought to be the source of rare but severe allergic reactions.³²

Transient bacteremia has been documented after barium enemas,³³ but no clinical problems have been reported. In patients with high-risk cardiac lesions such as prosthetic heart valves, it may be prudent to use antibiotic prophylaxis, as recommended by the American Heart Association.³⁴ This prophylaxis consists of 3 g of amoxicillin by mouth 1 hour before the study and 1.5 g by mouth 6 hours after the study.

In patients with severe ulcerative colitis, air and contrast medium rarely may enter the perirectal veins, and gas may even be seen in the portal vein.³⁵ This complication can occur as a fatal event.

Variations in Technique

SUSPECTED PERFORATION

When colonic perforation is suspected, the study should be performed with a water-soluble contrast agent such as

Figure 51-8 Complications of barium enema.

A. Rectal tear complicating barium enema with intravasation of barium into the wall of the rectum. **B.** Perforation of the intraperitoneal portion of the sigmoid colon in a patient with radiation colitis. Extravasated barium outlines the peritoneal cavity. **C.** Retroperitoneal air and pneumomediastinum are seen as a complication of a double-contrast barium enema in another patient with sigmoid diverticulosis (not shown on this view). (From Berk JE, Huubrich WS, Kalser MH, et al [eds]: *Bockus Gastroenterology*, 4th ed, vol 1. Philadelphia, WB Saunders, 1985.)

diatrizoate meglumine and diatrizoate sodium (Gastroview). If extravasation is not demonstrated, it may be prudent to repeat the examination with barium for better definition and detail. In patients with cystic fibrosis, a water-soluble enema can be administered for diagnostic or therapeutic purposes.³⁶ In such patients, the hyperosmolar agent draws fluid into the bowel that can liquefy viscous stool, sometimes with therapeutic results.

PERORAL PNEUMOCOLON

A peroral pneumocolon is sometimes performed in patients for whom the primary diagnostic interest is in the terminal ileum and cecum.³⁷ For this procedure, the patient undergoes preparation of the colon as for a barium enema. After orally administered barium has reached the right side of the colon, 1 mg of glucagon is administered intravenously and air is insufflated via a rectal catheter into the colon and refluxed into the

terminal ileum. This maneuver often provides excellent double-contrast views of the cecum and terminal ileum for better visualization of aphthoid ulcers and other abnormalities in these areas (Fig. 51-9).

COLOSTOMY ENEMA

Single- or double-contrast studies of satisfactory quality can be performed through a colostomy (Fig. 51-10).³⁸ This is particularly important for patients being followed after resection of a previous rectal carcinoma because of the increased risk of developing metachronous colon cancers at a later point in time. Barium may be administered through the colostomy stoma via a Foley catheter connected to an enema bag.

Contrast enemas after other types of colon surgery are discussed in Chapter 63.

Comparison with Other Methods of Examining the Pelvic Floor

Normal Variations

Summary

Pelvic floor disorders are an underdiagnosed source of morbidity and significantly diminish the quality of life. Most patients are women.¹ In any clinic that deals with pelvic floor disorders, about 80% of patients will be women between the ages of 35 and 50 years. Pelvic floor disorders are seen less frequently in men.

The demand for pelvic floor imaging is increasing. There are several factors that account for this, such as more patients seeking assistance, more physicians interested in this area, and more experience in the therapeutic options. Almost 24% of U.S. women complain of at least one pelvic disorder. The number of patients seeking assistance also increases with age, parity, and obesity.^{2,3} As the population ages, the need for pelvic floor imaging is expected to increase.⁴

The presenting symptoms of patients with pelvic floor disorders are variable. They can have anal incontinence, urinary incontinence and constipation. There may be prolapse of the rectum or vagina with a cystocele associated with any of these.

Anal incontinence ranges from constant soiling as a result of slow leakage, to the total inability to hold on to any stool in the rectosigmoid area. This latter group copes by emptying their

bowel at the faintest desire to defecate. They are therefore constantly emptying their bowel to avoid accidents. Overall, about 9% of women have fecal incontinence and 3% experience pelvic floor prolapse.² These signs and symptoms appear to be unrelated to the mode of delivery.⁵⁻⁸ However, parous women are not immune to functional pelvic floor disorders either.⁹⁻¹²

The presenting symptoms of constipation are also variable. This may be described as difficulty in initiating defecation, incomplete defecation, and considerable straining with defecation. Some patients may also complain that the stool is of inadequate size, weight, or water content. Patients who have difficulty in evacuation may use digital or positional maneuvers to assist in emptying the rectum. If this is not volunteered by the patient, it is useful to ask when taking a history prior to the examination because this information could be used to enhance the study.

Seemingly unrelated symptoms, such as bloating and abdominal pain, may also be related to pelvic floor disorders.¹³ Other apparently unrelated symptoms include dyspareunia, painful defecation, perineal pain, and rectal bleeding. Solitary rectal ulcer syndrome is often suspected when there is rectal bleeding.¹⁴⁻¹⁶

Preoperative identification of abnormalities causing pelvic floor disorder symptoms is important so that the appropriate surgery can be performed.¹⁷ This is especially true because one study has shown that there is a lifetime risk of 11% of at least one surgical procedure for pelvic organ prolapse and urinary incontinence and that the repeat surgery for recurrence is 29%.¹⁸

There is often a multispecialty involvement in the management of pelvic floor disorders. Radiologists, colorectal surgeons, gynecologists, and urologists may be involved. This chapter will only deal with the radiologic aspects.

Normal Anatomy

The pelvic floor is made up of the levator ani, urinary and anal sphincter mechanisms, and fascial supports of the pelvic viscera. The pelvic viscera include the rectum, vagina, bladder, and urethra (Fig. 52-1). An understanding of the structure and levels of pelvic floor support is important for the evaluation of pelvic floor dysfunction because this forms the basis of reconstructive surgery.¹⁹

There is an interaction between the colon and rectum in normal defecation. High-amplitude propagating waves that move fecal contents into the rectum stimulate the urge to defecate. As a result, the distention that this produces relaxes the internal sphincter through the anorectal inhibitory reflex in preparation for defecation. Defecation is then initiated by abdominal straining and voluntary pelvic floor relaxation whenever desired. Once the anal canal is open, the rectum is squeezed by abdominal contraction. About one third of the left colon and rectum is emptied in normal physiologic defecation.

Figure 52-1 Schematic depiction of normal pelvic anatomy. **A.** Axial schematic drawing shows the anatomic structures that provide pelvic floor support. A, Arcus tendineus fascia pelvis (white line). B, pubic bone; P, puborectalis; R, rectum; U, urethra; V, vagina. **B.** Sagittal schematic of the pelvis demonstrates various sites of prolapse, including the bladder neck and urethra (1), bladder base (2), cervicovaginal vault (3), cul-de-sac (4), and rectum (5). B, bladder; R, rectum; U, uterus. **C.** Drawing of the sagittal midline view of the female pelvis shows bony landmarks and the puborectalis muscle, also called the levator sling. The pubococcygeal, H, and M lines and levator plate are delineated in blue. (A and B from Pannu HK, Kaufman HS, Cundiff GW, et al: *Dynamic MR imaging of pelvic organ prolapse: Spectrum of abnormalities*. *RadioGraphics* 20:1567–1582, 2000; C from Fielding JR: *Practical MR imaging of pelvic floor weakness*. *RadioGraphics* 22:295–304, 2002.)

This is secondary to continued mass colonic contractions and likely additional proximal rectal contractions.²⁰

Pelvic floor anatomy is complex, and dynamic cystocolpoproctography (DCP) does not show the anatomic details that pelvic magnetic resonance imaging (MRI) provides. This consideration, predictions of a hypothetical increase in cancer incidence, and deaths in patients exposed to radiation and questions relating to the clinical significance of DCP findings have made pelvic floor MRI an important preoperative tool.

Several studies have compared CP and dynamic pelvic floor MRI.^{21–23} A recent evidence-based comparison has shown that DCP is the functional imaging study for anorectal dysfunction and pelvic floor prolapse evaluation.²⁴ This is because, in most existing MR units, the patient is imaged supine rather than upright, a deficiency negated by open architecture MR magnets.²⁵ This is an embarrassing examination and is made less acceptable when the patient is asked to defecate in an artificial environment and in an unnatural (supine) position where the patient is usually asymptomatic. Evacuation is pivotal

for the functional evaluation of the pelvic floor. Additional important factors are economics and practicality in everyday practice. In most institutions, the additional expense incurred with MRI compared with DCP and relative lack of accessible time on an MRI unit that is subject to heavy demand by other clinical specialties are important considerations. The logistics of performing a tailored examination (drainage of an undrained bladder and emptying of rectoceles) are important practical considerations when evaluating for the full extent of pelvic organ prolapse.

The use of an open MRI system with patients defecating makes it functional. With an open architecture magnet, however, one must contend with images of a lower signal-to-noise ratio and soft tissue resolution.²⁶ To make it a single noninvasive functional study to look at specific organ prolapses, specialized coils are needed to improve soft tissue resolution and visualize the pelvic supporting structures and fascial condensations directly. Specialized coils make dynamic pelvic MRI more intrusive. Dynamic pelvic floor MRI is an evolving technology, and

Figure 52-2 Normal rectum.

A. The normal rectum at rest. The anal canal is closed and there is a normal puborectalis angle. **B.** The rectum at defecation showing the anal canal totally open. A small rectocele is also present. This is normal during defecation as long as it totally empties at the end. R, rectocele; SB, small bowel; V, vagina with contrast.

its precise role in functional imaging of the pelvic floor still remains to be determined. It is likely that pelvic MRI with increased soft tissue resolution with endoluminal coils will complement the use of DCP when it is necessary to see structural details of the pelvic supportive tissues and endopelvic fascia for surgical management.²⁷ A static, high-definition MRI scan gives added information about muscle and/or ligamentous tears that may alter management, information that can only be inferred with DCP.

Defecation is initiated by descent of the pelvic floor. This can be seen on proctography as the anorectal junction descending from the resting position. As descent continues, the anal canal opens in the final moments. All this happens within seconds. Rapid emptying occurs when the anal canal is completely open. With the cessation of straining, tone returns to the anal sphincter and levator ani and the canal closes. The anorectal angle becomes more acute and the pelvic floor and anorectal junction return to their normal elevated resting position (postdefecation reflex; Fig. 52-2).

The pelvic floor is unlike other skeletal muscles. As a result of the continuous firing of motor units, even during rest, the pelvic floor has constant tone. This tone is only interrupted during defecation or urination. Therefore, a dynamic functional examination of the pelvic floor, especially to show the degree of prolapse, has to include defecation.²⁸

Assessment of Pelvic Floor

PREPROCEDURE PREPARATION

As with any procedure, it is extremely important to obtain a history of the patient's symptoms. Specific questions may have to be asked, such as the use of any maneuvers that may assist the patient. This is not always volunteered because the patient may be too embarrassed to disclose them.²⁹ Also, this is very intrusive, so the examination must be thoroughly explained prior to anything being done. This ensures that the patient understands the instructions given during the procedure.

Getting the patient to practice some of the maneuvers, such as squeezing the buttocks while sitting on the side of a stretcher prior to instillation of any contrast, is also useful. The patient should have maximum privacy and be comfortable as possible in the examination room. One way to achieve this is to use a remote control fluoroscopy unit, turning the lights down low and ensuring that the patient is the only person in the examination room.²⁰ In our unit, we also have blinds so that the patient cannot see the radiologist operating the remote fluoroscopy unit. Generally, if the patient is comfortable with the environment, the greater the likelihood of an accurate assessment of defecation.

IMAGING TECHNIQUE

Imaging of defecation was described as early as the 1950s.³⁰ It was not until the 1980s that Mahieu and colleagues described a technique that interested more radiologists.^{31,32} This technique has since been further modified with the addition of opacification of the small bowel, urinary bladder, and vagina.³³⁻⁴⁰ The opacification of these structures makes recognition of cystoceles, enteroceles, and sigmoidoceles easier. Preparation of the bowel with laxatives or enemas is not necessary, although some authors believe that a limited bowel preparation will be more comfortable for the patient and also provide a more standardized examination.⁴¹ The order of opacification is to give oral contrast first to opacify the small bowel. Usually, about 400 mL of contrast used for small bowel studies is sufficient. This is given about 45 to 60 minutes before the dynamic part of the examination. Some authors suggest waiting for up to 3 hours.³³ How long you have to wait depends on how long it takes for the small bowel contrast being used to opacify the pelvic loops of the small bowel.

Opacification of the urinary bladder is next, with water-soluble contrast normally used for cystography. About 150 to 200 mL of contrast is enough to make the bladder recognizable. Care must be taken not to overdistend or it could mask enteroceles. Overdistention is also uncomfortable for the patient.

The vagina is then opacified. This can be done with barium paste, high-density barium, or a thick solution of 50% contraceptive gel and 50% of water-soluble contrast with the highest concentration of iodide.⁴² The vaginal contrast is introduced with a bladder irrigation syringe connected to a soft catheter. A pediatric enema catheter works well. The catheter is inserted deep into the vagina and the contrast introduced as the syringe is slowly withdrawn. Care must be taken to ensure that there is sufficient contrast opacifying the whole vagina. In the past, a contrast-soaked tampon was used. However, it was noted that the tampon acted as a strut and did not allow any enteroceles, rectoceles, or sigmoidoceles to become apparent.

Finally, the rectum has to be opacified. It helps to have contrast material that has the consistency of stool or at least close to it. If it is too liquid, even normal patients will find it difficult to hold in the rectum.³⁴ Currently, there are no commercially made preparations available. The options are to use a thick esophageal paste such as Esobar (Bracco Diagnostics Inc., Monroe Township, New Jersey) or the thick paste, as suggested by Mahieu and associates.^{30,32} Three 50-mL syringes (150 mL total) of Esobar introduced into the rectum are usually enough to perform the procedure. When the syringes are filled, care should be taken to eliminate air bubbles because trapped air under pressure can cause discomfort to the patient (Fig. 52-3). The syringes are easier to fill if the paste is first warmed by holding the contrast tube under hot water. If the Mahieu preparation is used, it is useful to opacify the rectal wall first with contrast used for barium enemas. The doughy paste, if prepared as suggested, provides bulk but does not opacify the wall. Therefore, intussusceptions could be missed. The other disadvantage is that because of the consistency, it is difficult to introduce into the rectum. An orthopedic glue gun that is geared makes this thicker paste easier to introduce. To coat the rectal wall and fill the rectum with the Mahieu paste, attach a 50-cm length of 0.5-inch tube filled with high-density liquid barium to the glue gun, with a wide-bore enema tip at the end, so that both contrast agents can be introduced in one maneuver. The rectum is filled until the patient reports a sensation of fullness and a desire to defecate.

Finally, if you wish to measure the anal canal or determine the location of the anus, the surface around the anus should be opacified. This can be done with petroleum jelly opacified with barium. Petroleum jelly, 50 g, with 50 g of barium works well. This is smeared around the anus and along the natal cleft.

When the patient is ready for the study after all the contrast has been introduced, the patient is asked to sit on the defecography commode. The commode design should allow filming in lateral and frontal projections. A sturdy commode also dispels any fears that the patient may have about sitting on it. There are commercially available commodes but you can build one to your own design. A commode designed by Bernier and colleagues has a ruler in the midline so that direct measurements of the midline structures can be done if necessary.⁴⁰⁻⁴⁵ If a remote control fluoroscopy unit is used, the commode can be attached to the table top (Fig. 52-4). Positional changes of the commode can then be easily made by moving the tabletop. A remote control fluoroscopy unit is certainly preferable for this study.

The x-ray beam is aimed at the region of the reproductive organs. Therefore, keeping the radiation dose as low as possible is paramount. To keep the dose low, several investigators use only videofluoroscopy. Although the dose is low, the resolution is not adequate to record subtle radiographic changes. Therefore, it is recommended that videofluoroscopy be performed during the entire examination, with spot films being taken at key events. The key spot images are lateral views of the rectum at rest, lift (squeeze), cough, strain, defecation, and postdefecation. Other ways of reducing radiation dose include digital serial acquisition with one image/s for 30 seconds or using digital equipment with a low-dose program. Major reductions in radiation dose can also be achieved by slow pulsed fluoroscopy. Additional beam filtration can reduce radiation without impairing image quality.⁴⁴

The images at rest are taken without any conscious contraction of the pelvic muscles (Fig. 52-5A). On lifting (squeezing), there is maximal contraction of the pelvic floor musculature. This results in elevation of the entire pelvic floor (see Fig. 52-5B).⁴⁶ The muscles responsible for elevation of the pelvic floor are the puborectalis and levator ani. The anorectal angle

Figure 52-3 Supplies used during the examination. **A.** Syringe with a pediatric enema tip for the vaginal contrast, Esobar for the rectum, petroleum jelly with Vaseline as an anal marker, and lubricant. **B.** Other supplies that may also be used include a caulk gun to introduce contrast, contraceptive jelly with contrast for vaginal opacification, and commercially prepared rectal contrast. **C.** If the barium is not used for vaginal contrast, contraceptive jelly mixed with water-soluble contrast with the highest iodine content is used with a bladder irrigation syringe and pediatric enema tip.

Figure 52-4 Defecography commode. A. The commode for the procedure is attached to a remote fluoroscopy table so that the patient can be positioned using the tabletop movement. These steps make it easier for the patient to get to the seat. **B.** The dish in the commode has a radiopaque ruler (in centimeters) so that direct measurements can be made from the images. The dish is also covered with a plastic bag so that after each patient, all that needs to be done is to replace the bag. R, ruler.

Figure 52-5 Normal examination. A. Normal, at rest. The vagina (V) has a close relationship to the anterior wall of the rectum (R). The small bowel (SB) has been opacified. **B.** Normal with lift (squeeze). The anorectal junction is above the level of the ischial tuberosities and there is good contraction of the puborectalis (PR). **C.** Normal, with coughing. There is virtual no movement of the anorectal junction (ARJ). The bladder (B) and vagina (V) have been opacified. **D.** Normal, with straining (S). Again, the ARJ maintains a normal position and there is no incontinence. **E.** Normal beginning of defecation. The anal canal is open and there is good emptying. At the end, the rectum is almost totally empty, with some stray contrast remaining.

becomes acute with maximum elevation. The squeeze image demonstrates pelvic floor strength, and impaired movement may reflect puborectalis atrophy.⁴⁷ The anal canal simultaneously lengthens. These changes can be measured and are indicators of the continence mechanism. When asked to cough, the patient should produce a powerful cough in the rest position. This action simultaneously increases intra-abdominal pressure and contraction of the anal and pelvic floor muscles. In normal individuals, there is minimal or no descent of the pelvic floor and total continence (see Fig. 52-5C). When asked to strain, the patient should strain downward maximally, without evacuating (see Fig. 52-5D). This maneuver stresses the continence mechanism and provides a measure of pelvic floor descent. The anal canal shortens during straining in most women (mean change, 2 mm).⁴⁶ Almost all patients demonstrate some perineal descent, but this is the least reliable portion of the examination because some patients paradoxically contract the pelvic floor muscles, perhaps for fear of incontinence. Straining is supposed to demonstrate the competence of the external anal sphincter.

Finally, spot films are obtained during defecation and post-defecation straining (see Fig. 52-5E). These films give a measurement of pelvic floor descent and an estimate of the completeness of emptying. Morphologic abnormalities such as intussusception and rectoceles are often visualized at this time, and the changes contributing to difficulty in defecation can be analyzed. Rectoceles are outpouchings of the rectum beyond the expected contour of the rectal wall (Fig. 52-6). They are often normal and are more common in women.⁴⁶ If a rectocele

does not empty completely during defecation, it may produce a feeling of incomplete evacuation of the rectum.

Measurements

Measurements taken from spot films include the anorectal angle, anal canal length, level of the anorectal junction, and descent and elevation of the anorectal junction (see Fig. 52-10).

ANORECTAL ANGLE

The anorectal angle (Fig. 52-7) is measured between the axis of the anal canal and the tangent to the posterior wall of the rectum. It can be difficult to measure because the posterior wall of the rectum is often not clearly delineated, and the angle becomes highly subjective.⁴⁷ Caution should therefore be exercised when assessing its significance. At rest, this angle is usually no greater than 120 degrees in control subjects. However, the angle has a normal range of 70 to 134 degrees, with a mean of about 95 degrees.⁴⁶ When the patient squeezes or lifts the buttocks, the anorectal angle decreases to a mean of 19 degrees in women (range, 6 to 26 degrees) and a mean of 28 degrees in men (range, 12 to 45 degrees).⁴⁴ This angle increases during straining and defecation. The mean anorectal angle during straining in normal young women is 103 degrees, with a range of 75 to 108 degrees. In men, the mean angle is slightly lower, 98 degrees, with a range of 67 to 123 degrees.⁴⁶

ANAL CANAL LENGTH

The anal canal length is easily measured. It is the distance traversed by the parallel borders of the anal canal before they form the diverging walls of the distal rectum. At rest, the mean length

Figure 52-6 Rectocele (R). This is normal, except when it does not empty at the end of defecation. SB, small bowel; V, vagina.

Figure 52-7 Schematic showing the anorectal angle. The lines AB and CD subtend the posterior anorectal angle. The position of AB is easily determined; CD can be much more difficult to draw. The thicker line shows the position of the anorectal junction. Below it are the two parallel lines that form the anal canal. The thinner lines point to the puborectalis impression.

of the anal canal is 16 mm in women (range, 6 to 26 mm) and 22 mm in men (range, 10 to 38 mm). During lifting (squeezing), the anal canal lengthens to a mean of 19 mm in women (range, 9 to 26 mm) and 28 mm in men (range, 12 to 45 mm). During straining, the canal shortens slightly and has a mean length of 14 mm in young women (range, 6 to 20 mm) and 17 mm in young men (range, 9 to 27 mm).⁴⁶

LEVEL OF ANORECTAL JUNCTION

The anorectal junction is the uppermost point of the anal canal. Its position is measured from an easily visualized fixed point, the ischial tuberosity. A positive value indicates a position above the ischial tuberosity, whereas a negative value indicates a position below it. In normal young men at rest, the mean level of the anorectal junction is 16 mm and increases to 28 mm during lifting (squeezing). It drops to -4 mm during defecation. In young women, the mean values for the same maneuvers are 4 mm at rest, 14 mm during lifting (squeezing), and 16 mm during defecation,⁴⁵ measurements significantly different from those of normal young men.

Although these measurements can be made, in routine practice it is not done because of the poor reproducibility, especially the anorectal angle and descent of the anorectal junction.⁴⁸ Occasionally, unusual or unexplained findings are seen on lateral views, and anteroposterior or oblique views are needed for further clarification. Some patients have a history of using a variety of maneuvers to facilitate evacuation. These patients should be encouraged to use these maneuvers during the examination, and the mechanisms aiding evacuation should be identified. When patients have a large anterior rectocele that remains full even after the rectum has completely emptied, they may complain of incomplete emptying. These patients typically empty the rectocele back into the rectum by digital perineal or vaginal pressure. In patients with a history of obstructed defecation, it is sometimes helpful to perform the examination first with liquid barium, which makes expulsion easier. If this approach is successful, the examination should be repeated in the usual way with one of the thick barium pastes.

Pathology

ENTEROCELE AND SIGMOIDOCELE

Enterocoele refers to herniation of the small bowel into the posterior peritoneal cul-de-sac in the rectovaginal space or into the vagina itself. In some patients, both locations become filled with small bowel. Diagnosis depends on opacification of the pelvic small bowel and vagina (Fig. 52-8). The incidence of enterocoele has markedly increased as a result of the widespread performance of hysterectomy and cystourethropepy because both these procedures open up the posterior cul-de-sac. At hysterectomy, the uterosacral ligament complex or adjacent fascia is usually compromised. This leads to enterocoele formation and vaginal vault prolapse because damage occurs at the level of the vaginal apex. In one study,³⁸ defecography showed an enterocoele in 64% of patients who had undergone hysterectomy and 27% of those who had undergone cystopexy. Currently, hysterectomy is not considered a risk factor for future prolapse unless the hysterectomy was performed for prolapse.¹⁹ Patients with prolapse already have an underlying collagen tissue abnormality that predisposes them to further future prolapse. Urethropepy

Figure 52-8 Small enterocoele (E). The small bowel has just begun to enter the gap between the vagina (V) and rectum (R). The vagina and bladder (B) have also been opacified.

performed for incontinence predisposes to enterocoele formation by lifting the anterior vaginal wall forward and opening up the cul-de-sac. However, urethropepy has generally been replaced with the urethral sling procedure, which does not increase the frequency of enterocoele formation.¹⁸

Unlike rectoceles, which are generally largest during evacuation, enterocoeles (Fig. 52-9) usually become evident only at the end of evacuation because of the space occupied by the distended rectum. Repeated straining after evacuation may be essential for the recognition of enterocoeles. In one study,⁴⁹ almost half (43%) of the enterocoeles were seen only on post-evacuation radiographs obtained with the patient straining maximally, thus emphasizing the importance of this maneuver. Evacuation should be as complete as possible because the unemptied rectum or rectocele may prevent descent of an enterocoele. Obtaining a post-toilet radiograph (or postcatheterization radiograph in patients with urinary retention) to carry out further rectal evacuation offers the best opportunity to detect an enterocoele. Intravaginal enterocoeles, unlike those that extend into the rectovaginal space, often compete with a cystocele; if the cystocele is not sufficiently drained, the presence of a coexistent enterocoele may be overlooked or minimized. It should be noted, however, that enterocoeles may be overdiagnosed because of the lack of a clear imaging definition of the abnormality because the cul-de-sac can extend down the posterior vaginal wall by 5 cm.

The symptom typically associated with an enterocoele is a sensation of pelvic pressure or dragging, especially when standing or bearing down. Symptoms of vaginal prolapse, pelvic fullness, and lower abdominal pain have been shown to disappear

Figure 52-9 Large enterocele. A large enterocele develops if the patient has to strain because of difficulty in evacuation. This can then compress the rectum (R) and prevent further emptying. The bladder (B) has also been opacified. The opacified vagina can barely be seen.

after enterocele repair.⁵⁰ Enteroceles have long been held responsible for causing pressure on the rectum and obstructing rectal evacuation (the so-called defecation block).⁵¹ One study, however, has shown that enteroceles do not impair rectal emptying.⁵² Our observation is that it is the distended rectum, not the obstruction of the rectum by the enterocele, that prevents enterocele descent. Not uncommonly, an enterocele accompanies a rectoanal intussusception or rectal prolapse.

Surgical repair of an enterocele requires obliteration of the herniated, bowel-containing cul-de-sac, resuspension of the unsupported vaginal axis, and repair of other associated defects. Large enteroceles usually require a transabdominal approach so that a concomitant abdominal sacrocolpopexy procedure or similar vaginal suspension procedure can be performed. Defecography is important in this respect because the radiographic detection of a large, previously undiagnosed enterocele may change the surgical approach from a transvaginal to transabdominal route of entry. In many patients referred for defecography, this is the most crucial piece of information needed by the pelvic floor surgeon before surgery.¹⁸

A sigmoidocele is a redundancy of the sigmoid colon that extends caudally into the cul-de-sac.⁵² They are less common than enteroceles and are found on approximately 5% of proctograms.^{49,53,54} This condition will be underdiagnosed at proctography if the sigmoid is not opacified, but a sigmoidocele is suspected on the basis of widening of the rectovaginal septum and air seen within fecal residue. Lax presacral fixation of the rectosigmoid can be seen in some patients. As with other organ prolapses, there is no standard definition for sigmoidocele.⁵⁴ Fenner has defined a sigmoidocele as a sigmoid colon extending more than 4.5 cm below the pubococcygeal line.⁵⁴ According to our definition,²² such a finding would constitute a moderate-sized sigmoid herniation. Sigmoidoceles are usually not detected

Figure 52-10 Sigmoidocele and rectocele. This image shows a sigmoidocele (S) and rectocele (R). The vagina (V) has been slightly displaced by the rectocele, which has both air and contrast. The bladder (B) and small bowel (SB) have been opacified. The faintly seen anal canal has been marked (A; arrow).

at physical examination, even when large,²² and are often associated with constipation.^{53,54} The redundant sigmoid colon may compress the rectum and obstruct defecation. Stasis of solid debris in the redundant sigmoid may give rise to further discomfort and straining. A large rectocele may be combined with a sigmoidocele, which is known as a rectosigmoidocele (Fig. 52-10).

Sigmoid resection or sigmoidopexy has been shown to provide striking relief of associated constipation. Marked detachment of the sigmoid colon from the sacral hollow is suggestive of the need for concomitant sigmoidopexy. Because bowel surgery is often performed by a colorectal surgeon rather than a pelvic floor reconstructive surgeon, preoperative recognition of a sigmoidocele coexisting with other defects is important so that sigmoid resection or sigmoidopexy, obliteration of the cul-de-sac, and repair of associated pelvic floor defects can be accomplished at one surgical setting.

The term *peritoneocele* has been applied to herniation into the cul-de-sac⁵⁵ defined a peritoneocele as an extension of the rectouterine excavation below the upper third of the vagina. In the series by Bremmer et al., approximately 50% of peritoneoceles were found to contain bowel. In our experience, however, peritoneoceles usually contain small bowel. This probably reflects our routine use of the post-toilet strain sequence following emptying of any filled organ (bladder or rectum). This is readily demonstrated with dynamic MRI.²² A peritoneocele should be suspected at defecography if there is unexplained widening of the rectovaginal space (Fig. 52-11); we have found this on 9% of defecography images.⁴⁹ Recognition of a peritoneocele is important because it predisposes to enterocele formation and suggests the need for surgical closure of the cul-de-sac if reconstructive surgery of the pelvic floor is undertaken.¹⁸

As shown by vaginal markers, the vagina may separate from the anterior wall of the rectum during defecation (see Fig. 52-11), often causing the patient to feel pressure in the perineum.

Figure 52-11 Peritoneocele. A peritoneocele is suspected when there is a widening gap (*double arrow*) between the vagina (V) and rectum. The small bowel (SB) and sigmoid (S) have also been opacified.

Figure 52-12 Enterocoele. An enterocoele (e) is seen in the gap between the vagina (V) and rectum. There is also a rectocoele (r) present. This has been obstructed from further emptying by an intussusception (*curved arrow*).

When this separation is identified, the examination should be repeated at a later date, after the small bowel or peritoneum has been opacified, as described earlier.^{33,45} If the gap between the vagina and rectum is caused by an enterocoele, the opacified small bowel is seen descending (herniating) into a deep pouch of Douglas (Fig. 52-12). If rectal prolapse is also present, the small bowel may invaginate into the anterior rectal wall and prolapse with the rectum through the anal canal. A sigmoidocele can produce a similar appearance, so the proximal sigmoid colon must be opacified to allow differentiation. Occasionally, an enterocoele and sigmoidocele are present in the same patient (Fig. 52-13).

ANTERIOR MUCOSAL WALL PROLAPSE AND RECTOCELE

In anterior wall prolapse, the anterior rectal wall prolapses toward the external anal orifice during the final stages of evacuation. This prolapse is a frequent finding in women and may be responsible for isolating an anterior rectocoele. As noted, rectoceles are outpouchings of the rectal wall. They are usually anterior, reflecting a relative weakness of the rectovaginal septum. Rectoceles are often accompanied by an intussusception, which may obstruct defecation by occluding the anal canal and neck of the rectocoele.³¹ The anterior wall prolapse may precede an intussusception. Rectoceles are common in women who have had children. It is present in 78% to 99% of women who have given birth.^{56,57}

A rectocoele depth of less than 2 cm is usually considered clinically insignificant.⁴³ A rectocoele may be considered large if

the depth is more than 3.5 cm, as measured from the anterior margin.⁵⁸ Retained contrast material greater than 10% at the end of defecation is indicative of barium trapping. If the patient then believes that she has not emptied her rectum or uses vaginal or perineal pressure to empty the rectocoele, the rectocoele is abnormal. In other words, the size does not matter but symptomatic relief is relied on to make the diagnosis.

RECTAL INTUSSUSCEPTION

Rectal intussusception is a concentric invagination of the entire rectal wall that progresses toward the anal canal.⁵⁹ It is thought to cause rectal prolapse. The intussusception usually begins about 6 to 8 cm above the anal canal as an invagination of one of the valves of Houston.⁶⁰ The infolding of the intussusception is anterior in 62% of patients, annular in 32%, and posterior in only 6%. Minor degrees of infolding of less than 3 mm represent mucosal prolapse and are probably not significant. However, inferior extension of the intussusception into the anal canal is abnormal. When an intussusception plugs the anal canal, the patient may develop symptoms of obstructed defecation⁶¹ and solitary rectal ulcer.¹⁴ The patient sometimes learns to relieve the obstruction by pushing the intussusception plug back with a finger placed in the anal canal. Internal prolapse, as seen with an intussusception plug, is revealed only by evacuation proctography. Occasionally, it is demonstrated during the end of defecation, sometimes only with straining. Spot films depicting postdefecation straining are therefore important (Fig. 52-14A). Complete or external prolapses are clinically obvious (see Fig. 52-14B).

Figure 52-13 Simultaneous sigmoidocele and enterocele. **A.** Simultaneous presence of a sigmoidocele (S) and enterocele (E). The vagina (V) and bladder (B) have been opacified as well. **B.** Another patient with a sigmoidocele, enterocele, and cystocele (C). The bladder and vagina are opacified.

Figure 52-14 Enterocele, rectocele, prolapsed and intussusception. **A.** Postdefecation, there is an enterocele (E), obstructed rectocele (R), and some external prolapse. The vagina (V) has been opacified. **B.** In another patient, there is an intussusception (open arrow), external prolapse (straight solid arrow), and obstructed rectocele (curved arrow). This is the result of continued constant straining. The bladder (B) has been opacified.

Solitary Rectal Ulcer Syndrome

This is almost always associated with rectoanal or extra-anal intussusceptions. There is an increase in sphincter thickness on endosonography.⁶² The clinical findings are chronic straining, with blood and mucus. Endoscopy shows erythema or ulceration at endoscopy. The term *solitary ulcer syndrome* is misleading because erythema, a single erosion, or more than one ulcer may be present.¹⁵ With a double-contrast barium enema, thickening of the valves of Houston (rectal folds) is seen in most patients.¹⁶ However, the best indicators for surgical correction is a clinical or proctographic finding of rectal prolapse and the presence of a solitary rectal ulcer in association with rectal intussusception.⁶³

POSTERIOR-LATERAL RECTAL POUCHES

Posterior-lateral rectal pouches are herniations of rectal mucosa through the pelvic floor. They are often suspected on lateral

views but are confirmed on anteroposterior views during straining. These pouches are usually found in patients who have difficulty with rectal evacuation, which requires excessive straining. Patients who demonstrate excessive straining may have paradoxical contraction of the puborectalis sling or a nonrelaxing anal sphincter.

PELVIC FLOOR DYSSYNERGY (ANISMUS)

Pelvic floor dyssynergy, or anismus, is not a clear-cut diagnosis. Historically, pelvic floor dyssynergy has been diagnosed in those with a history of prolonged straining during defecation if there is inappropriate puborectal contraction and the patient is unable to expel a balloon filled with 50 mL of water. It was initially assumed that this would be shown during defecography as a persistent indentation posteriorly, just above the anorectal junction, but this finding has been poorly predictive of the diagnosis.⁶⁴ In the study by Halligan and associates,⁶⁴ prolonged and/or incomplete evacuation of contrast material was shown

to be a much more sensitive and specific finding; it was present in 83% of patients and none of the control subjects. The combination of prolonged and incomplete evacuation had a positive predictive value of 90% compared with a physiologic diagnosis of anismus. The cause of this syndrome (also known as paradoxical puborectalis contraction, incompletely relaxing puborectalis, and spastic pelvic floor syndrome) is unknown, although a convincing association with sexual abuse is suggestive of a psychological origin. Controversy surrounds its diagnosis. It cannot be demonstrated in many constipated patients and may be found in asymptomatic subjects; it has also been described as a laboratory artifact.⁶⁴ However, there seems to be a generally strong association with symptoms. Most convincingly, the success of biofeedback treatments in these patients supports the value of making this diagnosis¹⁷ and thus the importance of categorizing posterior compartment defects into functional and anatomic abnormalities. Slow colon transit may be improved as a secondary effect to the treatment of poor rectal emptying or by affecting cerebral gut innervation.⁶⁵

In patients with paradoxical contraction of the puborectalis, defecography shows an increased or unchanged anorectal angle during straining and defecation (Fig. 52-15). The puborectalis impression is usually prominent because of persistent contraction and increases when the anorectal angle is decreased. This syndrome is relatively common in patients with normal colonic transit and chronic constipation. Bartolo and co-workers found this syndrome in 11 of 49 patients who were examined by proctography.⁶⁶ As noted, it has also been called anismus and spastic floor syndrome.⁶⁷

In some patients, the puborectalis relaxes during defecation, but the internal or external anal sphincter muscle, or both, fails to open. Sphincters that fail to relax normally may be associated with anal fissures, spinal cord tumors, and painful hemorrhoids.

DESCENDING PERINEUM SYNDROME

Patients with the descending perineum syndrome also have difficulty defecating. This syndrome occurs when there is ballooning of the perineum below the plane of the ischial tuberosities during straining. Perineal descent is usually less than that of the pelvic floor and can be measured with a perineometer.⁶⁸ However, proctography is a more reliable method of assessing pelvic floor descent.⁶⁹ This syndrome may be seen in other

disorders involving obstructed defecation and may subsequently lead to injury of the pudendal nerve.

In younger patients, the pelvic floor is higher at rest and descends more at evacuation, whereas in older patients there is more descent at rest and less change at evacuation.⁷⁰ A low pelvic floor at rest is usually suggestive of muscle weakness and stretching of the elastic tissue in the fascial support.⁵⁶ In perineal descent syndrome, the anorectal junction is more than 3 cm below its normal resting position, as measured at the level of the ischial tuberosities. These measurements only apply if the study is done with defecation being observed in the normal physiologic position (i.e., sitting on a commode). When done with the patient in the left lateral decubitus position, the position of the pelvic floor is significantly higher.⁷¹ Therefore, this affects comparisons with other imaging techniques of the pelvic floor, such as MRI.

ANTERIOR MUCOSAL PROLAPSE

These patients present with bleeding, pain, and tenesmus. Progression to complications such as prolapse is uncommon.⁷² The characteristics of anterior mucosal prolapse at defecography is variable. A common finding is inversion of the anterior rectal wall over the anal canal with rectoceles.⁷³ Extension of the anterior wall into upper rectum without widening of the canal is suggestive of anterior mucosal prolapse (Fig. 52-16). One study has shown that anterior rectocele and perineal descent are present in 70% of women with anterior mucosal prolapse.⁷⁴ These findings are representative of total pelvic floor descent.

UTERINE AND VAGINAL VAULT PROLAPSE

In uterine prolapse, the uterus and cervix descend in the vagina and sometimes beyond the introitus. The cervix is the most distal point of the prolapse. Prolapse of the vaginal vault involves prolapse of the apex of the vagina through or beyond the introitus after a previous total hysterectomy.⁷⁵ Vaginal vault prolapse is almost always associated with prolapse of other pelvic organs; the most common is an enterocele. These associations usually reflect a loss of support because of damage to the uterosacral-cardinal complex. If the vagina is adequately opacified, the location of the cervix and/or vaginal apex can be determined on the strain images after evacuation by defecography.

Figure 52-15 Pelvic floor dyssynergy. **A.** This patient has pelvic floor dyssynergy or a nonrelaxing puborectalis (PR). The muscle can be seen to be prominent at rest. The vagina (V) and bladder (B) have been opacified. **B.** In pelvic floor dyssynergy, the puborectalis (PR) fails to relax sufficiently, as seen in this patient. With continued straining, a posterior rectocele (R) may appear. E, possible early enterocele.

Figure 52-16 Mucosal prolapse (arrows). V, vagina.

CYSTOCELE

A cystocele is diagnosed when the bladder base descends below the pubococcygeal line. It is the result of defects in the pubocervical fascia, which attaches laterally to the arcus tendineus and posteriorly to the cervix. The symptoms from a cystocele are minimal until it reaches the introitus. The most common symptoms are feelings of heaviness or “something bulging.” Voiding dysfunction may occur with large cystoceles.

Cystoceles are larger after rectal emptying and therefore optimally assessed by measuring the depth of the anterior vaginal wall at the end of defecation. If the vagina is well opacified, cystoceles can still be seen, without bladder opacification, by the downward displacement of the vagina. However, if the urinary bladder is too full, it may prevent the detection of a coexistent enterocele. Hypermobility of the bladder neck is diagnosed when the urethrovesical junction descends more than 1 cm from rest to strain, as measured on the postdefecation images (Fig. 52-17).

CONSTIPATION AND INCONTINENCE

Continuous straining stretches the pudendal nerve by causing ballooning of the pelvic floor. This stretching has been shown to increase motor latency of the pudendal nerve.⁷⁶ Continued straining can ultimately lead to permanent pudendal nerve damage and incontinence.

Normal control subjects have an anorectal junction level above the ischial tuberosity and an excursion of about 3 cm during straining and defecation. Constipated patients have a low anorectal junction level and good lift, but little or no movement during straining and defecation. Patients with fecal

Figure 52-17 Hypermobility of the bladder neck. C, cervix; R, rectocele; U, urethra; V, vagina.

incontinence have a low anorectal junction level (not unlike constipated patients), small lift, and large excursion during straining and defecation. Given that the constipated and incontinent patients both have low anorectal junction levels, it seems reasonable to speculate that these low levels are caused by constant straining and that constipated patients will eventually become incontinent as a result of a pudendal neuropathy. Because lift in the constipated group is still satisfactory, it may be possible to prevent incontinence in this group with a perineal support device, such as the Lesaffer seat (Defecom, Aalst, Belgium). The Lesaffer perineal support device⁷⁷ is designed to prevent excessive descent of the perineum, permit normal relaxation and expulsion, and prevent or minimize nerve damage.

Evacuation proctography for incontinence is of value only in patients with rectal prolapse, anal sphincter trauma, or neurogenic (idiopathic) incontinence. In rectal prolapse, patients are partially incontinent because the intussusception dilates the internal sphincter. When detected by proctography, rectopexy or a postanal repair can be performed.⁷⁸ In neurogenic or idiopathic incontinence, if the anorectal angle is widened, a postanal repair can correct this angle and restore continence.⁷⁹ In sphincteric trauma, proctography is useful for assessing the extent of damage to the pelvic musculature and monitoring healing.

Comparison with Other Methods of Examining the Pelvic Floor

Although incompetence of the internal and external sphincters or atrophy of the external anal sphincter can be predicted with rest, and strain images obtained at defecography,⁸⁰ this study cannot demonstrate the structural sphincter defects that are shown with anal endosonography⁸¹ and does not have the multiplanar imaging capabilities or soft tissue resolution

available with endoanal MRI.^{82,83} Several studies have compared defecography and dynamic MRI.²¹⁻²³ The conclusion by the investigators appears to be conflicting, and there is no consensus about which technique is superior for the evaluation of pelvic floor disorders. Dynamic MRI has considerable advantages.^{26,84} MRI provides a cine loop of pelvic organ and pelvic floor descent. The multiplanar representation has the potential to yield much more anatomic information about the pelvic floor musculature and support structures. It has the advantage of no ionizing radiation. The mean effective dose for defecography has been estimated to be 3.2 ± 2.7 mSv.⁸⁵ The risk with this dose is unknown, but the Health Physics Society⁸⁶ has stated that the risk for developing radiation-induced cancer with doses in this range are too small to measure or are nonexistent. Also, in the age group referred for defecography, radiation should not be a consideration.

Dynamic MRI also has major disadvantages. In most MRI units, the patients are imaged in the supine rather than upright position (this does not apply when imaged in a vertical open magnet).²⁵ In the horizontal magnet, the patient is therefore asked to defecate while lying supine, an unnatural position. A position in which patients are usually asymptomatic, and in an artificial environment, makes an embarrassing examination less acceptable. Evacuation of the rectum is pivotal in this study; if an open vertical magnet is not available, fluoroscopic defecography is preferable.

Additional factors that have to be considered are economics, practicality in everyday practice, and the advantages of one modality over another. In most institutions, the additional cost of MRI versus conventional defecography and the relative lack of time on the MR unit as a result of other clinical demands are major disadvantages.

Normal Variations

The abnormal findings in evacuation proctography, as noted, are much easier to characterize than normal findings. This difficulty in defining normal characteristics is because there are limited data on normal subjects in different age groups⁸⁷ and

only one study of normal volunteers.⁴⁴ The latter study by Shorvon and associates showed that the range of normal characteristics is much greater than originally reported. Several investigators agree that the normal mean anorectal angle is between 90 and 100 degrees.^{31,33,56,88} In the earlier study, the anorectal angle in normal young volunteers had a range of more than 60 degrees around this mean. The same study showed a mean pelvic descent of 2 cm; however, pelvic descent was greater than 5 cm in some women and 4 cm in some men. Many investigators believe that a pelvic descent of 3 to 3.5 cm between rest and defecation is abnormal; this position has been confirmed by clinical estimates.⁸⁹ This discrepancy may be related to the fact that clinical estimates are obtained with the patient lying on a couch in a horizontal lateral position. In this position, the patient may be inhibited from maximal straining for fear of incontinence. In addition, the added weight of the rectal contents that contributes to the downward pull of the pelvic floor is absent. Furthermore, the proximal radiographic anal canal probably becomes incorporated into the distal rectum during evacuation as it forms a cone configuration. These factors increase apparent pelvic descent during evacuation proctography. In the study by Shorvon and co-workers, it was also surprising to find that rectal intussusception occurred in normal subjects.⁴⁵ However, none of these patients had external prolapse.

Summary

In conclusion, evacuation proctography can often provide a unique functional perspective of disorders of defecation, particularly those relating to constipation and obstructed defecation. Some of the problems depicted by this examination are amenable to surgery, and others can use nonsurgical options such as biofeedback and pelvic floor exercises (Kegel exercises). However, because there is considerable overlap between normal and abnormal appearances, it is important to recognize the value of anal manometry, electromyography, colon transit studies, and the patient's clinical findings before making any management decisions.

Summary

Computed tomography colonography (CTC) is a low-dose, cross-sectional imaging examination optimized for the detection of colorectal polyps and masses. As a result of advanced computer 3D postprocessing, a popular misperception is one of an imaging analogue to optical colonoscopy in which a 3D model is used to view the mucosal surface of the interior of the colon. However, CTC is fundamentally a different examination, using 2D images and 3D datasets in the interpretation of mucosa, deeper structures, and even processes beyond the colon. Since its introduction in 1994, CTC has matured into a clinically effective modality. Central to this transition are technologic advances in computer hardware and software that have allowed the easy acquisition and manipulation of large volumetric CT data sets. Performance in low polyp prevalent screening populations has now been validated in a number of prospective clinical trials,¹⁻⁵ with a general consensus that CTC performs substantially better than double-contrast barium enema⁶ and is equivalent to optical colonoscopy for clinically relevant polyps and masses.

This chapter will provide a comprehensive overview of this modality. The technical components that comprise the examination, including bowel preparation, colonic distention, and image acquisition, as well as alternative CTC approaches such as noncathartic or laxative-free (previously mislabeled as

“prepless”) protocols, will be discussed. Interpretation will be covered in detail, including common strategies currently in use. The mechanics of interpretation will be highlighted, with coverage of the more common and important pitfalls that can affect the accuracy of this process. The indications and uses for CTC will be examined, outlining the optimal screening target and the polyp-carcinoma sequence that forms the underlying rationale of the selective polypectomy strategies for CTC-based screening. In addition to screening, diagnostic applications for CTC and the evaluation of colorectal cancer (CRC) staging will be covered. Finally, pertinent issues central to CTC will be examined, including radiation dose, complications, and extracolonic (incidental) findings.

Technical Components

CT colonography is a multicomponent examination that is undertaken over several days. The major technical components include bowel preparation, colonic distention, and image acquisition. A programmatic or team approach is favored because it allows each portion of the procedure to be optimized for reproducible, high-quality examinations. Thus, a nurse program coordinator can answer patient questions on bowel preparation in the days prior to the scan to minimize preparation failure, and the technologist can optimize the bowel distention while the patient is on the scanner table. The radiologist can interpret the examination and forward the results for further coordination of care to be undertaken by the program nurse. Such division of labor allows the radiologist to concentrate totally on interpretation. Without a team approach, the technical components are often addressed in a less complete fashion. A breakdown in any study component ultimately limits the potential impact of the overall examination.

The traditional approach to CT colonography involves a fully cleansed and tagged colon. Alternate methods have been investigated, including laxative-free techniques, but large multicenter validation studies remain to be done. Once the colon has been prepared, it is distended with gas (carbon dioxide or room air) and finally imaged with a low-dose, thin collimated technique in a minimum of two patient positions. The following sections outline the principles and major strategies in use for the technical components of the examination. In addition, common problems that may arise will be addressed. The protocol at the University of Wisconsin (UW) is highlighted as one specific solution.

BOWEL PREPARATION

The objective of this first portion of the examination is to prepare the colorectum for optimal imaging. Traditionally, this involves oral administration of a cathartic agent to purge the

colon of fecal matter that could mimic or obscure a colonic polyp. Tagging agents are also administered orally to admix with any remaining stool and colonic fluid. Contrast agents increase the attenuation of stool and fluid to allow easy differentiation of soft tissue polyps from stool and detection of polyps submerged in fluid (Fig. 53-1). Bowel preparation is typically undertaken 1 to 2 days prior to the scheduled examination. The specific agents and protocol used in bowel preparation often vary among different institutions.

Cathartic agents have traditionally been classified as dry or wet preparations. Both types are in use with CTC. Dry preparations result in only minimal residual colonic fluid and include low-volume osmotic cathartics, such as magnesium citrate; wet preparations often result in larger amounts of residual fluid, occupying up to 50% of the lumen in various segments. Wet preparations include polyethylene glycol (PEG) and formulations based on PEG. Early on, there was an emphasis placed on using dry cathartic preparations with CTC to minimize obscuring polyps by residual fluid.⁷ At this time, tagging agents were not typically used, and any unopacified fluid would obscure a submerged polyp. Although the polyp should theoretically be seen when the patient was imaged in a complementary position (i.e., supine vs. prone), it could be missed when detected only on one view, and the examination became considerably more tedious and difficult to interpret because of the difficulty in determining which portion of the colon mucosa had been interrogated and what remained to be seen. With the addition of colonic tagging, such considerations regarding the amount of residual fluid have become less important because the polyp can

be seen as a soft tissue structure in the high-density colonic fluid (see Fig. 53-1). On the other hand, some reports have suggested that dry formulations remain advantageous over wet preparations because they may promote the phenomenon of polyp contrast coating.⁸ There is increasing recognition that polyp coating is an important aid in polyp detection, particularly those of a flat morphology (see later, "Interpretation").

The major cathartic agents currently in use include magnesium citrate and PEG. Magnesium citrate is an osmotic cathartic agent. It is one of the dry cathartics in which relatively small amounts are ingested and work by means of an osmotic effect. Because of its hypertonicity, fluid is pulled across the colonic mucosa into the colonic lumen. The fluid then serves as an effluent that lavages out the colon. Because of this mechanism of action, it mandates that the patient be well hydrated before catharsis; otherwise, the cleansing action is less than optimal. Furthermore, it is important to maintain hydration throughout the preparation period to maintain effective cathartic action and decrease the possibility of dehydration. Holte and associates have shown that osmotic cathartics can cause significant volume loss over the preparation period, during which a median weight loss of 1 kg was seen, despite fluid intake of 4 L in a series of healthy volunteers.⁹ Typically, a multidose magnesium citrate regimen is undertaken with CTC (e.g., two doses separated by a predetermined time interval) to allow optimal cleansing.¹⁰ Single-dose regimens have shown less effectiveness and more poor preparation outcomes.¹¹ Magnesium citrate has long been used for barium enema examinations,^{12,13} and there is considerable experience with its use in this regard. It is well

Figure 53-1 Advantages of fluid and stool tagging.

A. Supine 2D CTC image with fluid tagging allows easy visualization of a submerged polyp (arrowhead), which was a tubular adenoma at colonoscopy (inset). **B.** Without fluid tagging in another patient, the grey appearance of the fluid (arrowheads) in the cecum would obscure submerged polyps. **C.** Supine 3D CTC image shows a possible sessile polyp, which is easily confirmed as stool (2D inset) because of tagging, which increases the internal attenuation values to create a white appearance (arrowhead). **D.** Without stool tagging, stool (arrowhead) mimics a polyp with a grey appearance, requiring demonstration of movement. Note the dependent location between the supine and prone series.

tolerated, with a favorable safety profile.¹²⁻¹⁴ It can be used in almost all patients aside from those with severe renal dysfunction and those with tenuous fluid balance control.

PEG is a wet-based preparation. In addition to standard PEG, several related formulations are in use with CTC, including Miralax and HalfLytely. PEG is a balanced solution with various electrolytes and a high molecular weight, nonabsorbable polymer that prevents secretion or absorption. Large volumes (4 L) are ingested to create the effluent. PEG is considered the safest of cathartics and can be used even in debilitated, fluid-tenuous patients because negligible fluid and electrolyte shifts occur across the colonic mucosa. When completed, this preparation leads to excellent catharsis in most patients. The major drawback has been compliance with the preparation because of decreased palatability. One study showed that up to 38% of patients failed to complete the entire preparation.¹⁵ As noted, because of its wet preparation nature, there is often a fair amount of residual colonic fluid.

Sodium phosphate is an osmotic cathartic agent that was used widely in the past but is no longer favored. It is mentioned for historical reasons and to highlight its potential dangers. Until 2008, it was one of the major cathartic agents in use for CTC and optical colonoscopy because of its excellent cleansing abilities and high compliance rate. Patients were more likely to complete the regimen, which required ingestion of a small-volume solution or ingestion of multiple pills. However, sodium phosphate had a narrow therapeutic range, with a higher incidence of complications. In 2004, a rare but generally irreversible form of renal failure was identified with sodium phosphate use mediated by a precipitation of calcium phosphate in the renal tubules (so-called phosphate nephropathy).¹⁶ After recognition of this potential complication, a black box warning was issued by the U.S. Food and Drug Administration in 2008, and this agent now requires a prescription. For CTC, sodium phosphate and formulations that contain sodium phosphate are typically no longer used.

Tagging agents include barium formulations and iodine-based solutions. For barium, there are two common densities used, a dilute 2% w/v preparation (CT barium) or a much denser 40% w/v preparation. The primary action of barium is to tag particulate stool internally. It admixes with the stool to increase the attenuation substantially from 40 to 60 HU to well over 200 HU, allowing for easy identification from soft tissue (see Fig. 53-1). Barium can also tag fluid but tends to do so inhomogeneously, with a gradient effect related to gravity, in which the more dependent portions of the fluid are more densely tagged. Iodine-based agents are ionic (e.g., diatrizoate) or nonionic (e.g., iohexol, iopamidol). The primary action is to tag residual colonic fluid (see Fig. 53-1). It can also tag stool but often does less well than barium-based agents in this regard. There is considerable variation in tagging approaches. Some CTC protocols use a single tagging agent (barium or iodine alone), and others use a two-agent approach (both barium and iodine) to take advantage of the benefits of each.

The UW protocol is one of several that have demonstrated excellent results for bowel preparation on a consistent basis, with nondiagnostic rates related to bowel preparation with CTC much less than 1%.¹⁷ The specific protocol is outlined in Table 53-1. It is predicated on the principles of complete colonic catharsis and tagging of residual stool and fluid. The cathartic choice has been magnesium citrate because of its palatability in comparison to PEG. A double-dose regimen is required to

TABLE 53-1 University of Wisconsin Bowel Preparation

Time*	Agent	Amount	Comment
8 AM	Clear liquid diet	Maintain hydrated state. [†]	Beginning with breakfast
11 AM	Bisacodyl (Dulcolax)	2 tablets orally [‡]	Stool softener
3-5 PM	Magnesium citrate	300 mL (one bottle)	Cathartic [§]
After 3 hours, administer	Magnesium citrate	300 mL (one bottle)	Cathartic
	2% w/v Barium sulfate	250 mL (one bottle)	Tagging
After 3 hours, administer	Diatrizoate	60 mL	Tagging
9-11 PM	Preparation is complete for the examination the following morning.		

*Prior to 8 AM, the patient is NPO after midnight.

[†]It is important to maintain hydration to optimize the cathartic action. Recommend hydration prior to cathartics and at least 4-6 cups of liquid with each of the osmotic cathartic

[‡]Does not require the patient to be near a bathroom. Catharsis begins with administration of magnesium citrate.

[§]If polyethylene glycol is substituted, the first dose should be given around noon (16 8-oz cups, one every 10 minutes, for a total of 4 L).

cleanse the colon adequately.¹⁰ As opposed to some protocols, the cathartic is given prior to tagging (as opposed to the reverse situation) to purge the bulk of the stool and increase the effectiveness and efficiency of tagging; a wider window for optimal tagging exists for a given amount of tagging agent. With the reverse situation, larger amounts of tagging agents are needed to tag the bulk colonic contents.

A dual tagging approach is preferred (as opposed to a single agent) to take advantage of the benefits of each agent—barium for stool and iodine for fluid. The dilute formulation of barium (2% w/v) is used in the UW protocol. The 2% version tags the residual stool particles well and is not too dense with CTC. As opposed to the denser 40% preparation, this formulation has not obscured visualization of colonic mucosa or clogged colonoscopic ports; this is important because most patients with CTC-detected polyps undergo same-day colonoscopy to take advantage of the prepped status. Regarding the second tagging agent, the ionic nature of diatrizoate is preferred over a non-ionic solution, despite its less palatable taste. In addition to tagging residual fluid, the increased osmolarity of the solution works like a mild second cathartic, resulting in a final cleansing of the colon. This action is particularly important when a dry cathartic agent is used in the protocol. From the barium enema era, it was noted that use of magnesium citrate promotes excessive barium coating.¹⁸ In the case of CTC, without the final cleansing action of diatrizoate, this can lead a right-sided studding or even a thick film of tagged stool (Fig. 53-2). This pitfall often precludes the use of 3D CTC for polyp detection in this situation (see later), which can lead to decreased sensitivity for lesion detection. It is thought that the substitution of nonionic iodine solutions could lead to a similar situation, in which the final hypertonic cleansing does not occur.

Finally, and perhaps most importantly, the combination of the three agents in this protocol (magnesium citrate, 2% barium, and diatrizoate) appears to promote a polyp-coating phenomenon (Fig. 53-3). The tag appears to adhere to the mucosa

overlying the polyp (CTC equivalent of a polyp etched in white at barium enema) while it is washed away from the normal colonic mucosa.⁸ It is postulated that there is an interaction between a negatively charged mucin film elaborated by polyps and the positively charged barium tag. The diatrizoate washes the tag away from normal mucosa but not from the polyp surface. This phenomenon has been very helpful in detecting polyps, particularly those of a flat nature, which are only

minimally raised from the colonic surface. Whether this phenomenon is reliably seen with wet-based or iodine-only preparations is unknown.

COLONIC DISTENTION

The objective of this portion of the examination is to distend the colorectum optimally to allow the easy detection of

Figure 53-2 Importance of diatrizoate. **A.** Supine 2D CTC image shows right-sided studding of tagged stool in a patient who did not take all the diatrizoate. Note the impact on 3D (*inset*), where it would be difficult to assess for polyps. **B.** Without diatrizoate (in a second patient), this can even lead to a diffusely tagged coating of the mucosa.

Figure 53-3 Polyp-coating phenomenon. **A.** 3D CTC image shows a sessile polyp. Note the thin barium coat (*arrowhead*) overlying the polyp (*inset*) whereas it has washed away from the colonic wall (*arrow*). **B.** A 10-mm tubular adenoma confirmed at colonoscopy. **C.** 3D CTC image shows a flat polyp (*arrowheads*), which is etched in white (*arrow*) on the 2D inset, increasing conspicuity. **D.** Flat hyperplastic polyp seen at colonoscopy.

intraluminal projections and true wall thickening, but also to balance the degree of distention with acceptable patient discomfort. With optimal distention, the colonic walls are well separated; the walls are thin and almost imperceptible. Thus, polyps are well delineated as they project into the colonic lumen. The high contrast between the gas-filled lumen and soft tissue nature of the polyp allows for even many small diminutive polyps to be seen. It is important to realize that the colon does not have to be completely distended on a given series to be diagnostic in nature. It can be partially underdistended on a single series. However, the corresponding series often shows excellent distention in the same area because of the complementary shifting of gas to nondependent regions, allowing for an interpretable examination (Fig. 53-4). When needed, a decubitus series can be helpful.

There are two gaseous agents available for colonic distention. Of these, carbon dioxide is favored over room air because it is actively absorbed across the colonic mucosa and eventually expelled by the respiratory system. Reduced instillation pressures essentially preclude perforation and promote patient comfort.¹⁹⁻²¹ Because the colon rapidly decompresses, the patient feels relief very quickly after the instillation ceases. In

contrast, room air is composed chiefly of nitrogen, an inert gas in which there is no active reabsorption. Because of this, manual instillation pressures can be very high, with the possibility for perforation. In addition, patients can feel uncomfortable and bloated for several hours after colonic distention with room air until it is passed through the gastrointestinal (GI) tract.

The major strategies for colonic distention include manual room air insufflation and automated carbon dioxide insufflation. Room air insufflation was initially the primary method for distention with CTC. There was considerable prior experience with barium enema, and the equipment was inexpensive and readily accessible. This was undertaken with manual bulb insufflation after the insertion of an enema tip. The air was introduced by staff or by patient self-insufflation. However, there are several major problems with this CTC strategy that led to less than optimal examinations. Most importantly, unlike with barium enema, there was no real time assessment of the degree of colonic distention. With barium enema, distention adequacy could be determined at fluoroscopy. With CTC, no real-time visualization is possible; adequacy was surmised by a set number of puffs relative to patient body habitus or by patient feedback to distention discomfort. Therefore, colonic distention was

Figure 53-4 Complementary shifting of gas. **A.** Supine CTC scout shows apparent good colonic distention. **B.** However, 2D CTC image shows a collapsed, fluid-filled sigmoid segment (arrowhead). **C.** Adequate evaluation of this area can be accomplished because of shifting of gas and fluid on the prone series, resulting in good distention (arrowhead).

variable, dependent on the administering staff and the patient's individual perception of or tolerance to distention. Also, this was a very labor-intensive method that required individual coaching for each case. In addition to the difficulties of distending the colon, there was the possibility of perforation because fairly high wall pressures could be generated with this "blind" administration. Most institutions have since moved to automated carbon dioxide (CO₂) insufflation because of difficulties with room air insufflation and several recognized advantages with the use of CO₂. However, because of the inert nature of room air, in which there is no active resorption, room air can be used to distend segments that are resistant to CO₂.

CO₂-based distention involves the use of an automated insufflator. Because CO₂ is actively resorbed, it requires continuous low-pressure instillation, which can only be undertaken with automated delivery. After insertion of a small-caliber, flexible-tip catheter, CO₂ is instilled at low pressures, regulated by the machine. During the filling phase, intracolonic pressures (as measured by the insufflator) generally range from 11 to 19 mm Hg. The pressures may transiently increase to 35 to 40 mm Hg with positional change or if colonic spasm occurs, but will quickly decrease as the spasm resolves. At some point, the pressures settle in a range of 20 to 28 mm Hg (with volume measurements typically at 3.5 to 4.0 L) and an equilibrium state is achieved—the CO₂ inflow balances the ongoing losses (resorption by colonic mucosa, as well as potential loss around the catheter and/or reflux into small bowel). At this point, the colon is typically optimally distended. The benefits of this equilibrium state are that it can be maintained as long as the CO₂ remains infusing, and it is easily identified by viewing pressure and volume measurements on the machine console. Thus, distention is much more reproducible and less labor-intensive with this approach. In addition, because of the low-pressure delivery, in which maximum pressures rarely exceed 50 mm Hg for a few moments, complications are almost nonexistent (see later).

The use of spasmolytics is controversial. Glucagon, a polypeptide pancreatic hormone with smooth muscle relaxant effects, has shown mixed results, without definite improvement in distention or improved patient comfort.^{22,23} In addition, it has been reported to increase the incidence of small bowel reflux. It is typically not used with CTC in the vast majority of U.S. institutions. However, in Europe and Canada, Buscopan (hyoscine butylbromide) is widely used. This anticholinergic agent acts on the postganglionic parasympathetic smooth muscle receptors to cause colonic relaxation. Several studies have shown increased distention and patient comfort, however, without a significant increase in polyp detection.^{23,24} Contraindications include a history of glaucoma. It is not available in the United States.

The UW distention protocol is outlined in Table 53-2. Patient discomfort is minimized by setting the instillation pressure at 17 to 18 mm Hg for the average-sized individual, which is adjusted upward as needed. The key for optimal distention is to attain and maintain an equilibrium state prior to imaging. As noted, this is determined by assessing pressure and volume measurements recorded by the insufflator (21 to 29 mm Hg and 4 L, respectively). One key point to optimizing distention is related to volume. Although equilibrium pressures can be seen with volume measurements at 2 L, it has been preferable to wait until 3.5 to 4 L has been reached (Fig. 53-5). In our experience, persons are often imaged too quickly before full distention because of high-volume concerns and the possibility of perforation. It is important to understand that the volume recorded by

TABLE 53-2

University of Wisconsin Distention Protocol

Volume (L)	Pressure (mm Hg)	Patient Positioning and Comments
0.0	0.0	Insert rectal catheter with patient in LLD and inflate balloon.
0.0-2.0	10-19	Fill with patient in LLD.
2.1-4.0	10-19*	Roll RLD and continue filling.
4.0+	20-30	At equilibrium, turn supine to scout and scan.
4.0+†	20-30	Roll prone and do quality check of supine series.
4.0+†	20-30	Wait until equilibrium is reestablished; then scout and scan prone series.
4.0+†	20-30	Quality check of prone series and determine need for decubitus series
6.0-8.0‡	20-30	Typical volume and pressure at end of examination

*May rise to 20 to 30 mm Hg suggesting equilibrium but continue to fill until volume reaches 3.5 to 4 L. If pressures rise to 30 to 40 mm Hg, transient spasm is likely.

†Continuous infusion throughout required to maintain equilibrium. Volume should continue to rise.

‡May see volumes exceeding 10 L if patient has loss around catheter or incompetent ileocecal valve.

LLD, left lateral decubitus; RLD, right lateral decubitus.

the machine does not represent the amount in the person's colon because there is continuing ongoing loss (see earlier). Equilibrium is reached when the infusion is matched by the loss; thus, the low-pressure instillation could be extended indefinitely. As such, it is important to wait until the volume measurements reach about 4 L, even if equilibrium pressures (20 to 25 mm Hg) are attained earlier to allow full distention. Typical recorded volume measurements at the conclusion of the examination range from 5 to 6 L although it is not uncommon to have numbers in the range of 10 to 12 L. The CTC technologist is an important person in this part of the examination; real-time quality assurance checks are carried out by this trained individual to determine whether additional imaging is required (e.g., a decubitus series).

Some common distention difficulties include machine- and patient-related factors. Active problem solving, however, can often salvage an otherwise suboptimal examination. One common situation is frozen or unchanging pressure and volume measurements, in which it does not appear that carbon dioxide is infusing. The cause is an obstruction at some level, usually in the tubing. In addition to factors such as lying on the tubing, a common cause is a column of fluid in the tubing, which can block the CO₂ infusion because of the low-pressure nature of instillation. The patient will often report that the bowel preparation was started late. Once the tubing is cleared of fluid, the infusion will restart. Other situations, in which CO₂ infuses but does not optimally distend the colon, may be related to almost empty tanks or to the patient's underlying colon and decreased distensibility from conditions such as diverticular myochosis or frank stricture.

IMAGE ACQUISITION

Once the colon is optimally distended, the patient is scanned. At a minimum, two series are obtained, with the patient in supine and prone positions. Each series is undertaken in end-expiration to minimize the extrinsic compression of the lungs

Figure 53-5 Distention at 4 L versus 2 L. **A.** Scout CTC at 4 L shows excellent colonic distention. **B.** Scout CTC at 2 L in the same patient at repeat routine screen 5 years later shows less distention. Although both examinations at 4 L (**C**) and 2 L (**D**) are diagnostic, note how the decreased distention (**D**) leads to prominence of the haustral folds and deeper troughs between them, which may contribute to decreased polyp detection.

on the transverse colon. The datasets should be immediately evaluated to ensure that there is adequate distention and that no colonic segment is collapsed on both views. If this occurs, an additional series (typically with the patient in a right lateral decubitus position) can be undertaken.

CTC represents a low-dose, thinly collimated, and typically noncontrast examination. The optimal parameters represent a balance between maintaining polyp visualization while minimizing dose. Thus, although submillimeter collimation is possible, overlapping 1.0- to 1.25-mm slice thicknesses are adequate, given that the examination positivity size threshold is set at 6 mm for CTC. Overall, the required parameters for the examination are not stringent, and high-quality CTC results can be obtained with basic multidetector CT (MDCT) scanners. As opposed to examinations such as cardiac CT, in which high temporal and spatial resolution are needed (to image small-caliber cardiac vessels on a beating heart), the high-contrast nature of soft tissue polyps projecting into a gas-filled lumen and the static nature of the colon allow the use of standard 16-slice MDCT scanners. The scanning parameters of the UW protocol are given in Table 53-3. Dose exposures are approximately 3 to 5 mSv for the examination.

TABLE 53-3 University of Wisconsin Computed Tomography Colonography Scan Parameters

Parameter*	GE LS VCT 64
Detector configuration	64 × 0.625
Rotation time (sec)	0.5

Interval (mm)	0.75
kV	120
Smart mA/auto mA range	30-120
Noise index	50

*Specific parameters represent a snapshot in time.

ALTERNATIVE PROTOCOLS

In addition to the standard cathartic-tagging regimen, considerable interest has centered on alternative protocols that minimize or eliminate the cathartic portion of the bowel preparation. The cathartic requirement for CRC screening modalities has long been recognized as a major barrier in colorectal cancer

screening compliance.²⁵⁻²⁷ Noncathartic or laxative-free CTC holds the possibility of substantially increasing screening rates by appealing to those who currently refuse screening because of purging requirements. Whether polyp sensitivity can be maintained in this situation is an area of ongoing research.

The typical approach of this modified CTC protocol is to use a low-fiber diet followed by the ingestion of tagging agents. Often, the protocols are multiday regimens, so the popular monikers of “prepless” or “minimal prep” CTC are a misnomer. There is a bowel preparation regimen but the cathartic aspect has been removed. The colon is distended in a fashion similar to that for standard CTC. Often, postprocessing in the form of electronic cleansing or digital subtraction of the tagged feces is used. Single-center feasibility studies have shown excellent results in high-polyp prevalence cohorts.^{28,29} Recently, a multicenter prospective trial in a low-prevalence screening cohort reported per patient sensitivities of 91% for adenomas at the 10-mm threshold, with decreased sensitivities of 59% at the 6-mm threshold.³⁰ This study highlights the current tradeoff with noncathartic protocols. Although perhaps more appealing to patients, there is a real decrease in sensitivity for polyp detection by laxative-free CTC versus the standard cathartic and tagging protocol, particularly for smaller subcentimeter polyps. In addition, these studies are more difficult to read, requiring expertise in distinguishing a postprocessing digital subtraction artifact from subtle polyps at 3D or relying on primary 2D approaches alone.

Interpretation

Once the technical aspects of the CTC examination are complete, the datasets can be networked to a workstation to allow 2D and 3D review. The main objective of interpretation is to identify soft tissue polyps and exclude pseudopolyps, typically related to retained feces or thickened folds. There is general consensus that an unavoidable learning curve exists for CTC.^{31,32} CTC interpretation requires the traditional cross-sectional skills from CT as well as additional CTC-specific skills for accurate interpretation. Two major strategies were initially proposed, defined in terms of detection: (1) a primary 2D approach with 3D problem solving; and (2) a primary 3D approach with 2D confirmation. Most recently, a combined approach has been favored. All detection strategies ultimately use a common characterization pathway, and the process of interpretation (regardless of specific detection approach) can be broken down into two major tasks, as described here.

There are two general tasks of interpretation with CTC. The first is one of detection, in which focal intracolonic structures that potentially represent a polyp are identified (with 2D or 3D review). Once a list of possible polyps is established, the second task is characterizing each of these possible polyps—the soft tissue polyps are confirmed and the pseudopolyps are excluded. It is this step in interpretation in which the true skill in interpretation resides (i.e., achieving high specificity is more challenging than high sensitivity). If this cannot be done well, too many patients are sent on to colonoscopy for false-positive CTC examination results from pseudopolyps. Young and colleagues have shown that nonradiologists can detect potential polyps with similar sensitivities to radiologists at the 8-mm threshold but at the expense of specificity (78% vs. 92.2%, respectively). This suggests that nonradiologists do not have critical cross-sectional characterization skills.

The property of polyp coating from tagging agents is an important phenomenon that has now been recognized.⁸ It positively affects detection and characterization, perhaps most importantly for flat polyps. As noted earlier (see “Bowel Preparation”), tagging agents adhere to true polyps while are washed away from the normal mucosa. This serves to draw attention to possible polyps, particularly on the 2D view, and helps increase confidence that a polyp is real (by demonstrating this property). One pitfall is not to mistake poorly tagged stool or adherent plaques of tagged stool as coated polyps (see later, “Characterization”).

DETECTION

Regarding detection, there had been a heated debate in the literature about the optimal method, a primary 2D approach or primary 3D approach.³³ A primary 2D approach consists of interrogating a stack 2D dataset, typically in the transverse plane (Video 53-1). The mechanics are similar to viewing a standard CT, in which the reader scrolls interactively through a stack of images in polyp window settings (2000 W, 0 L). The colon is traced from rectum to cecum with the intent of detecting focal soft tissue projections into the colonic lumen. The difficulty of this approach is distinguishing between a focal polyp and colonic haustral fold. On a single image, a colonic fold can present as a focal polyp; it requires scrolling through to ascertain its elongated nature (Fig. 53-6). Once experienced, the reader can be very effective at quickly detecting polyps by this approach. However, it requires sustained concentration, which can be somewhat tedious. The 2D search pattern is analogous to detecting pulmonary nodules on a chest CT and distinguishing them from pulmonary vessels.

Additional videos for this topic are available online.

A primary 3D approach uses postprocessing of the 2D dataset into a 3D perspective. The reading mechanics are completely different and involves traveling through a tubular 3D environment, typically on a preprogrammed course (see Video 53-1). When needed, the reader can then break off this fly-through to interact freely in this 3D environment and visualize an area of concern from any angle. The 3D approach holds the advantage that differentiating potential focal polyps from colonic folds is easily done from this perspective (see Fig. 53-6). The mental translation into a 3D structure that is needed for a primary 2D approach has been undertaken by a computer. Whereas from a 2D perspective, a haustral fold can appear polyp-like until assessed in detail, such is not the case at 3D where they are instantly recognizable as different entities. A disadvantage of this approach is that 3D relies on surface morphologic cues only as compared to the 2D approach, which uses morphologic and attenuation cues simultaneously. Thus, any retained stool, despite its tagged status, would appear as a polyp at 3D and require evaluation of the 2D source data for confirmation. Also, areas of colonic collapse or segments with residual fluid are not well evaluated with a 3D approach, and the reader may not be aware of their existence on that series. Typically, however, 3D evaluation is possible on the complementary series as fluid moves away and gas distends these areas on the second series.

The standard 3D viewing option is an endoluminal perspective. Traditionally, a fly-through consists of passage from the

rectum to the cecum and then from the cecum to the rectum to allow both sides of the colonic folds to be visualized. Often, the field of view is widened at 120 degrees. In addition to the standard endoluminal view, there are alternate advanced 3D displays in use, including the filet view, unfolded cube, and band view (Fig. 53-7). These increase visualization (behind folds) and

thus speed of interpretation, but at the cost of increased spatial distortion.

Despite the prior controversy regarding detection approaches, there is now general consensus that a combination of 2D and 3D is required for optimal polyp detection. In practice, it has become obvious that the approaches are

Figure 53-6 Polyp versus haustral fold at 2D. **A.** 2D CTC image shows the difficulty of distinguishing a polyp (arrowhead) from a haustral fold (arrow) on a single image, where they are similar in appearance. **B.** This is not a perceptive concern at 3D, where the haustral morphology (arrow) is clearly different from a polyp (arrowhead). The red line corresponds to the level and orientation of the 2D image.

Figure 53-7 Advanced 3D displays. The filet (**A**), unfolded cube (**B**), and band view (**C**) allow examination of both sides of the colonic folds simultaneously to detect a polyp (arrowhead), but at the cost of spatial distortion. (**A** and **B** from Pickhardt PJ, Kim DH: *CT Colonography: Principles and Practice of Virtual Colonoscopy*. Philadelphia, Elsevier, 2010; **C** courtesy Seong Ho Park, MD.)

complementary; polyps or masses that are difficult to visualize by one perspective are easily seen by the other. For the 2D approach, there are some polyps that project off the colonic mucosa or off the end of the fold at an angle relative to the axial plane that are difficult to detect because the reader perceives the polyp as a fold or an extension of the fold (Video 53-2). In addition, polyp shape at 2D can cause difficulties in detection (Video 53-3). Both situations are not problem areas at 3D. For 3D, polyps submerged in the polyp pool can be missed (Video 53-4). In addition, underdistended areas can make the determination of lesions difficult because the walls become irregular as a result of their partially collapsed state. Focal areas of collapse related to an annular cancer with the 3D approach can be misinterpreted and missed if not evaluated with a 2D approach (Fig. 53-8). By combining 2D and 3D detection, the complementary nature of the approaches allows a polyp to be seen when not evident by one perspective. In addition, the added redundancy of interacting with the imaging dataset multiple times during a combined approach further decreases the possibility of missing polyps.

 *Additional videos for this topic are available online.*

Figure 53-8 Collapse at 3D.

A. 3D CTC map shows two innocuous areas of collapse. The 3D endoluminal view (inset) of the inferior collapsed area is unremarkable. One segment (arrow) is simple collapse but the second (arrowhead) is not. **B.** The 2D CTC image depicts the annular cancer (arrowhead), which would be easily ascertained during 2D detection review.

Figure 53-9 Polyp confirmation.

A, B. Supine and prone 2D CTC images show that this cecal polyp candidate (arrowhead) meets the criteria for a true soft tissue polyp. Note the homogenous grey appearance on both views and the fixed location, where it does not fall to a dependent location on either position. There is a thin etching of contrast overlying the polyp (the polyp coating), which is common with the UW bowel preparation.

CHARACTERIZATION

Characterization of suspected polyps is the second and perhaps most important step in interpretation. Each detected polyp candidate must be evaluated to determine if it actually represents a polyp and exclude pseudopolyps related to retained stool or thickened folds. A true soft tissue polyp must fulfill two criteria (Fig. 53-9; see Video 53-1). First, it must be homogenous soft tissue in attenuation when viewed in polyp window settings (2000 W, 0 L). There should be a uniform grey appearance similar in density to the adjacent musculature on all series as opposed to untagged stool, in which internal heterogeneity exists. At times, feces can demonstrate internal homogeneity, particularly small, subcentimeter-sized pieces. However, these pseudopolyps can often be ascertained as they are often mobile in the colorectum (see later, second criterion). Tagged stool is easily determined by its markedly increased attenuation (see Fig. 53-1).

The second criterion relates to a fixed location between the various series. The polyp candidate must be attached to the colonic mucosa at a single point and cannot move. In contrast, stool will fall to a dependent location between the series. Thus, a true soft tissue polyp must be homogenous in attenuation and

fixed in location on all series. When these criteria are used, the concordance at optical colonoscopy is well over 90%.^{34,35} These determinations are made by evaluating the 2D source images and only minimally by the 3D postprocessed dataset (3D tools such as translucency rendering can help in attenuation determination). The ability to confirm suspected polyps accurately requires a strong cross-sectional skill set and grounding in CT principles. There are several pitfalls that can cause misinterpretation, including beam hardening, apparent movement of polyp, and underlying colonic movement. In addition, incompletely tagged stool can at times mimic a coated polyp.

Beam hardening is an important phenomenon that can affect characterization (Fig. 53-10). Because of the low doses used with CTC, beam hardening can cause apparent heterogeneity of soft tissue polyps or even a fatty appearance if adjacent to high-density structures such as tagged fluid pools or bone. Flat polyps are particularly affected by this phenomenon given their lack of soft tissue bulk, in which they have such an appearance because of streak from the overlying contrast coat. It is important to recognize this phenomenon to prevent mischaracterization of a polyp for stool related to its altered internal appearance.

Differentiating apparent movement of a true polyp from a moving pseudopolyp related to untagged stool is key. One

well-recognized pitfall is related to pedunculated polyps with an elongated polyp stalk (Fig. 53-11). If this is not recognized, the polyp head can be mistaken for a sessile polyp candidate. Because it moves with changes in patient position, this true polyp can be mistaken for moving stool. At times, the 3D approach can be helpful to identify the stalk.

Additionally, the colon can shift, move, and twist in position, particularly those segments on a mesentery (cecal apex, transverse, sigmoid). It requires solid localization skills with a 2D approach to confirm that the polyp candidates seen on both views represents the same colonic location because of the shifting underlying colon (Fig. 53-12). The reader must use the few internal landmarks, such as a stray diverticulum, characteristic bend, or haustral fold, to trace the colon in this area to confirm that the candidate is at the same location between the various series. When possible, the ileocecal valve is an excellent landmark to use for polyp candidates in the right colon. One important underrecognized pitfall is the ability of the cecum and ascending colon to rotate on its long axis.^{36,37} There is often a counterclockwise rotation between the supine and prone position, despite the retroperitoneal location of the ascending colon and portions of the cecum. This can cause apparent movement of the polyp candidate (Video 53-5).

Figure 53-10 Beam hardening.

A. 2D CTC in soft tissue windows suggests that a submerged pedunculated lesion (arrowhead) may be a lipoma. This is an artifactual appearance related to beam hardening from the contrast fluid pool. **B.** The true soft tissue nature of the polyp (arrowhead) is seen on the decubitus view, where the contrasted fluid moves away. **C.** Supine 2D CTC image in another patient with a flat polyp (arrowhead), where beam hardening from the contrast coat and fluid pool on the prone image (**D**, arrowhead), which creates an artifactual fatty appearance of this proven soft tissue polyp.

Figure 53-11 Pedunculated polyp simulating movement. **A.** 2D CTC image shows a focal soft tissue structure (arrowhead) in the sigmoid colon. **B.** It may be mistaken for stool, given apparent movement to the dependent wall on the prone series (arrowhead). **C.** 3D CTC image is helpful for identifying the stalk (arrow) of a pedunculated polyp to avoid this pitfall.

 Additional videos for this topic are available online.

Finally, although the coating phenomenon is very important in improving polyp detection and characterization, it is important to recognize that incompletely tagged stool can mimic a coated polyp (Fig. 53-13). With close inspection, there are slight differences where the interface between the polyp and barium coat is sharper and better defined than for stool. The easiest way to distinguish stool is mobility—the tagged stool will move between the supine and prone positions. In these cases, when there is a question between a coated polyp and incompletely tagged stool, the fecal debris tends to be large and not adherent.

POLYP DIFFERENTIAL

At interpretation, the practical differential is between a true soft tissue polyp and pseudopolyp (related to stool or a thickened fold).³⁸ It is not necessary to determine the histology of the polyp (which cannot be determined with CTC or optical colonoscopy) because management is driven by polyp size.³⁹ However, it is important to be aware of the possibilities and future cancer risk for each histologic subtype once it is known

at pathologic evaluation. Polyps typically arise from the mucosal surface. The major histologic subtypes include adenomatous polyps, hyperplastic polyps, and mucosal polyps (in order of decreasing frequency). Adenomatous polyps account for approximately 50% of all polyps, hyperplastic a third, and mucosal 10%.⁴⁰ Although benign, a tiny fraction of adenomatous (and recent evidence also indicates hyperplastic polyps) can progress to cancer over many years.

Deeper lesions from the submucosa, intramural layer, or extrinsic to the colon can present as polyps indistinguishable from mucosal originating lesions. These include lipomas, carcinoid, lymphangiomas, and GI stromal tumors. However, as with principles at barium enema, the lesions can be suggested when they demonstrate obtuse sloping margins, suggesting a deeper origin.

As noted, histologic diagnosis cannot typically be undertaken by imaging. Mucosa-based polyps (adenomas, hyperplastic polyps, mucosal polyps) and deeper colonic lesions present as nondescript focal lesions of soft tissue attenuation. However, image-specific diagnoses can be made in a few rare circumstances without pathologic evaluation, such as a lipoma. Lipomas arise from the submucosal layer but often appear as

Figure 53-12 Movement of underlying colon. **A.** 3D CTC map shows an elongated, tortuous sigmoid with a polyp candidate (red dot) in the mid-sigmoid. **B, inset.** Supine 2D CTC image shows a 7-mm polyp (arrowhead) arising from the nondependent wall. **C.** Note the changed appearance of the sigmoid with polyp (arrowhead) on the prone series because of underlying movement on its mesentery. Without appropriate cross-sectional skills, it may be difficult to confirm that this lesion is fixed in location and represents a soft tissue polyp.

Figure 53-13 Coated polyp versus tagged stool pitfall. **A.** 2D CTC prone image shows a nondependent structure consistent with a polyp with a thick overlying barium coat. Colonoscopy (inset) confirmed a large villous adenoma containing a well-differentiated adenocarcinoma. **B.** Note the similar appearance of incompletely tagged stool. Movement (supine on left side of image, prone on right side) confirms that this is stool.

sessile or even pedunculated lesions of presumed mucosal origin. An image-specific diagnosis can be made when a fatty internal density is seen (Fig. 53-14). In other circumstances, a diagnosis can be highly suspected in entities such as endometriosis, dependent on clinical and imaging factors (Fig. 53-15). This diagnosis can be suggested when a nonspecific soft tissue, broad-based lesion with smooth obtuse margins is seen in a younger female. The overlying folds are often not disrupted. These lesions represent serosal implants that have extended into intramural and submucosal layers. Colonoscopy is often helpful to exclude a mucosal lesion that appears submucosal on CT.

REPORTING

Reporting is a central element in interpretation. C-RADS (CT colonography reporting and data system) is a structured reporting construct in use since 2005. Colonic and extracolonic findings are classified separately by C and E categories (Table 53-4). This allows for standardization of approach and management,⁴¹ which then allows for comparison between institutions clinically and in research.

On the colonic side, C-RADS standardizes polyp sizing, location, and reporting of morphology. For measurement, the longest axis of the polyp is used. For pedunculated lesions, the

longest axis of the polyp head is measured (with exclusion of the stalk). Standardization of sizing is particularly important because polyp management is dependent largely on size. Location is divided into the six colonic segments of cecum—ascending, transverse, descending, sigmoid, and rectum. Polyp morphology includes sessile (dome-shaped, with a broad base of attachment), pedunculated (polyp head with a stalk of variable length attaching to the colonic mucosa), and flat (plaque-like appearance with a height ≤ 3 mm from the colonic surface). Masses are 3 cm or larger.

On the extracolonic side, each finding is classified by clinical significance and the need for further evaluation. By definition, E1 and E2 examinations will not require additional work-up, whereas E3 and E4 can lead to further imaging. The final E category is determined by the most advanced lesion if there are multiple findings. The extracolonic issue is covered in additional detail later in this chapter.

Computer-Aided Detection/Diagnosis

CAD (computer-aided detection or diagnosis) software devices use mathematic algorithms to identify specific patterns in radiologic images. Because the primary objective with CTC involves a repetitive defined task operating within a large dataset, there is considerable interest in using CAD to improve

Figure 53-14 Submucosal lipoma. **A.** 3D CTC image shows a broad-based lesion with obtuse, sloping borders. **B.** Translucency rendering (3D attenuation tool) shows a green signature suggestive of fat. **C.** 2D CTC image confirms the diagnosis of a lipoma (arrowhead).

Figure 53-15 Endometrioma. **A.** 3D CTC image shows an apparent submucosal or deeper lesion with obtuse borders. **B.** 2D CTC image shows a nonspecific soft tissue lesion (arrowhead) but in the appropriate clinical situation and history, a diagnosis of endometrioma can be made.

TABLE 53-4

C-RADS

Parameter	Description	Recommendation
Colonic		
C0	Inadequate study or awaiting comparisons	—
C1	Normal colon (no polyp ≥ 6 mm)	Routine screen (5 yr)
C2	Isolated small polyp (one or two 6- to 9-mm polyps)	Imaging surveillance up to 3 yr versus immediate colonoscopic removal
C3	Polyp, possibly advanced adenoma (≥ 10 mm or \geq three 6-9 mm polyps)	Colonoscopic removal
C4	Colonic mass, likely malignant	Surgical consult
Extracolonic		
E1	Normal examination or anatomic variant	—
E2	Clinically unimportant finding (e.g., hepatic or renal cyst)	No work-up indicated
E3	Likely unimportant; incompletely characterized	Work-up may be indicated
E4	Potentially important finding (e.g., solid mass or aneurysm)	Work-up indicated; communication to referring physician

C-RADS, CT colonography reporting and data system.

interpretation. CAD is potentially helpful by reducing perceptual errors (errors in which polyps are not perceived initially but can be identified in retrospect) related to fatigue and inattentiveness on the part of the radiologist. Ultimately, however, the radiologist must have a strong interpretative skill set to determine which CAD prompts represent true polyps; otherwise, the use of CAD simply increases sensitivity at the expense of specificity, without a true improvement in accuracy.

Although the specific algorithms are unique to each CAD system, all systems have some common steps. First, the dataset is postprocessed to facilitate CAD application and may include elements such as edge enhancement and sharpening of interfaces. The area of interest (i.e., the colorectum) is segmented out and a set of specific features are calculated for each voxel. Examples of possible features include shape, size, and curvature. The number and specific features used are different with different CAD systems. These features are then entered into a classifier, which may be a neural network, kernel machine, or decision tree to calculate a numeric value representing the likelihood that the prompt represents a polyp. If the CAD system is intended to be a detection device (CADE), there is a binary reporting of positive or negative according to whether a certain threshold is met; CAD systems intended for diagnosis (CADx) presents likelihood information.

The impact of the use of CAD software is difficult to assess. Stand-alone device performance can be excellent, with sensitivities of 90% for large (≥ 10 mm) polyp and variable lower sensitivities, ranging from 61% to 92% at the 6-mm level, with false-positive marks of 2 to 14 per patient.⁴²⁻⁴⁵ However, ultimately, it is the interaction between the CAD device and radiologist that determines overall performance. There is conflicting evidence whether CAD improves interpretation. Petrick and associates have shown that although sensitivities increased by 15% at the 6-mm threshold versus unassisted reads, it was at the expense of specificity, which decreased by 14%.⁴⁶ Thus, there was no actual improvement but simply a shift in the set point of what was called positive. In contrast, Dachman and co-workers reported true improvement with a small but statistically significant increase in the segment level area under the receiver operating curve (AUC; $p = 0.015$).⁴⁷

CTC Trial Results

CTC performance has been well established by a number of trials in high-polyp prevalence groups and low-prevalence screening cohorts. The high-polyp prevalence population studies represented initial proof of concept studies. Typically performed as single-institution series, these studies showed that CTC could detect polyps with high sensitivities, albeit in the least difficult situation, in which a large percentage of

examinations were positive.⁴⁸⁻⁵² One notable study from this group was a prospective trial from Boston University published in the *New England Journal of Medicine* in 1999. Fenlon and colleagues⁵⁰ enrolled 100 high-risk individuals to undergo both CTC and colonoscopy evaluation. Despite using now older technology and protocols (including no fecal tagging, room air distention, and 5-mm image collimation reconstructed at 2-mm intervals), CTC demonstrated a 91% sensitivity (20 of 22 polyps) at the 10-mm threshold, which decreased to 82% (33 of 40) for 6- to 9-mm polyps. All cancers in the series (3 of 3) were seen with CTC.

The positive results seen in these small, single-institution series then paved the way for large multicenter trials in low polyp prevalence or screening cohorts. These studies assessed whether CTC performance could be maintained in the more challenging and pertinent clinical situation in which most of the examinations would be negative. Here there were discrepant results, leading to controversy regarding the true capabilities of this modality. First, Pickhardt and associates reported the results from the multicenter Department of Defense (DoD) CTC trial in 2003.² In a large cohort ($N = 1233$ screening individuals, three institutions), the per-patient sensitivity for adenomatous polyps was 94% at the 10-mm threshold, decreasing to 89% at the 6-mm threshold. In comparison, optical colonoscopy sensitivity was 88% at the 10-mm level and 92% at the 6-mm level. The lower than traditionally reported sensitivity levels for colonoscopy were likely related to trial design, in which an enhanced polyp validation system of segmental unblinding was used. In contrast to using colonoscopy in isolation as the gold standard, in which colonoscopy misses would be unaccounted, segmental unblinding created an enhanced reference standard in which the CTC results were revealed segmentally at colonoscopy. Thus, if no polyp was initially seen at colonoscopy but noted with CTC, the colonoscopist reexamined the segment for the missed polyp. Such a standard led to more accurate sensitivity and specificity measures for both modalities, correcting the situation in which a false-negative colonoscopy result would be inaccurately counted as a CTC false-positive.

Following the DoD results, however, two smaller multicenter trials demonstrated much poorer results.^{53,54} Rockey and co-workers ($N = 614$)⁵⁴ and Cotton and colleagues ($N = 615$)⁵³ reported poor sensitivities, ranging from 55% to 59% for large polyps (≥ 10 mm) and decreasing to even lower levels for sub-centimeter polyps. At the time, this led to great debate about the adequacy of CTC performance. However, with the results of the subsequent larger validation trials published several years later, it is now evident that the Rockey and Cotton trials were flawed, accounting for the poorer trial results. In addition to using older CTC technology, one major criticism concerned the lack of reader training. For example, the Cotton trial required no prior reader experience or training for the CTC readers. It is now evident that there is a learning curve for CTC interpretation that requires acquisition of CTC-specific skills in addition to existing CT cross-sectional skills. Liedenbaum and associates demonstrated such a learning curve in which substantial improvement among novice readers was seen through a study set of 200 CTC cases.³¹ Sensitivity increased from an initial value of 76% at the 6-mm threshold for the first set of 50 CTC cases to 91% sensitivity for the fourth set of 50 cases. Furthermore, studies suggested that training and experience may not be enough, and that competency testing may ultimately be required.⁵⁵

During this evaluation period of CTC performance, it is important to be aware that CTC was a dynamic technology with continuing changes in the underlying CTC software, hardware, and examination protocol. Technical components were refined, leading to more optimally prepared and tagged bowel, improved and consistent colonic distention, and increased spatial resolution with decreased artifact.^{7,10,56-65} The CTC protocol evolved, such as standardizing the use of both supine and prone imaging for the typical examination, with additional decubitus series for problem solving.^{59,66,67} Underlying improvements in computer hardware allowed easy manipulation of even larger volumetric datasets. The current CTC examination, as noted earlier, now reflects the tremendous advancements over the years.

In 2008, the results of the ACRIN 6664 protocol or National CT colonography trial were published, answering the controversy about the discrepant initial screening results. This landmark trial validated the prior excellent results seen by Pickhardt and co-workers.² It was a large multicenter trial ($N = 2531$ participants, 15 institutions) performed in a low-prevalence or screening cohort. It used state of the art techniques and required a high level of experience and competence testing by the readers. In this trial, a per-patient sensitivity of 90% and specificity of 86% was seen for large polyps (≥ 10 mm). The performance decreased to a sensitivity of 78% at the 6-mm threshold. In addition to the ACRIN trial, other series in Europe corroborated a high level of CTC performance. The Italian IMPACT trial ($N = 937$, 12 institutions)³ showed a 90.8% sensitivity (84.5% specificity) at the 10-mm threshold, and the Munich Colorectal cancer screening trial⁴ also showed similar results (92% sensitivity, 98% specificity). The United Kingdom SIGGAR trial demonstrated equivalent detection rates for cancers and large polyps between CTC and colonoscopy screening programs.⁵

Outside of trial data, actual results from large-scale clinical practices suggested that CTC-based screening could be effective.⁶⁸⁻⁷¹ A large Wisconsin series by Kim and colleagues reported results from parallel operating CTC ($N = 3120$) and colonoscopy ($N = 3163$) colorectal cancer screening programs, in which each drew from the same regional population.⁷⁰ The CTC program reported advanced neoplastic yields equivalent to the colonoscopy program ($n = 123$ CTC; $n = 121$ colonoscopy) but with a fourfold decrease in the number of polypectomies (561 vs. 2434) and subsequent marked decrease in the number of complications (0 vs. 7 perforations). In addition, outcomes data from the negative CTC screening cohort ($N = 1050$) from this program have also been reported. Patients with a negative screen who were followed over a 5-year interval showed a very low interval cancer rate of 0.2 cancers/1000 years of patient follow-up, suggesting that setting examination positivity at a 6-mm threshold and routine screen interval at 5 years is a safe practice.⁷²

Indications and Use

There are three broad categories of use for CTC: (1) screening for colorectal cancer; (2) focused evaluation for various diagnostic reasons, including incomplete colonoscopy; and (3) simultaneous colonic evaluation and distant staging of initially diagnosed CRC or surveillance of known CRC. Many of the indications previously undertaken by barium enema have been now supplanted by CTC at many institutions.

SCREENING FOR COLORECTAL CANCER

Screening for CRC is perhaps the most important indication for CTC, for which its use could have a major public health impact. CRC currently is the second leading cause of cancer in the United States; there are approximately 143,000 new cases/year, leading to almost 52,000 deaths annually.⁷³ It is estimated that of the 80 million U.S. adults eligible for screening, only slightly over 50% participate with any of the traditional options, including optical colonoscopy, fecal occult blood test (FOBT)—fecal immunochemical test (FIT), flexible sigmoidoscopy, and double-contrast barium enema (DCBE).^{74,75} In addition, there are concerns regarding population screening capacity for options such as optical colonoscopy.⁷⁶ This is further accentuated by the growing awareness that specialized GI capacity is uneven and is dependent on geographic region, which is particularly limited in rural areas.⁷⁴ Thus, CTC has the potential to increase screening adherence substantially by appealing to currently noncompliant persons^{77,78} and by increasing the screening capacity, particularly in rural underserved areas (where examinations can be conducted at the local hospital and networked to central areas of expertise for interpretation).⁷⁹

Screening is particularly effective in decreasing CRC mortality because of several favorable factors in its biology: (1) CRC has a stepwise progression, from a benign precursor lesion to cancer; (2) the benign precursor can be identified and removed; and (3) the benign precursor has an extended latent period (10–15 years) prior to transformation to cancer, leading to a wide window for intervention. As opposed to other cancers, such as breast cancer, in which the intent is to detect early cancer to affect future mortality, CRC screening represents true primary prevention, in which the removal of a benign lesion precludes the future development of a cancer.

The benign precursor lesion for CRC arises from a subset of colonic polyps from adenomatous and hyperplastic lineages. Transformation from benign adenomas represent the major pathway, accounting for an estimated 85% of sporadic cancers, and hyperplastic or serrated polyps may account for the remaining 15% of cancers.^{80–82} It has only recently become apparent that hyperplastic polyps hold the possibility of malignant transformation; previously, they were considered to be completely innocuous lesions. Adenomatous polyps typically undergo genetic changes in several key genes, including *APC*, *k-ras*, and *p53*, whereas serrated or hyperplastic polyps undergo a newly discovered pathway mediated by a mutation in the *B-raf* oncogene, followed by epigenetic changes to this cell signaling pathway and microsatellite instability. It is important to realize that only a tiny minority of adenomatous and hyperplastic polyps ultimately go through the entire pathway to cancer; the vast majority regress or remain benign adenomas or hyperplastic polyps. Thus, although up to 40% of adults older than 50 years may harbor adenomas,^{83–85} and approximately 10% to 30% harbor hyperplastic polyps,^{86,87} only a relatively small fraction ends up with cancer. Risk factors suggesting that an adenoma or hyperplastic polyp may progress include larger size (>1 cm) or high-grade dysplasia.^{82,88–90} For adenomas, a villous architecture also increases risk for progression.⁸⁹

Because of these findings, the screening strategy with CTC is based on a selective polypectomy approach; this differs substantially from the universal polypectomy approach with optical colonoscopy, in which all soft tissue polyps regardless of size are removed. In contrast, CTC follows a strategy in

which the higher risk polyps, identified by large size, are initially removed and the polyps at low risk for transformation are followed. Of the low-risk group, those that increase in size at follow-up are then removed, whereas the stable and regressing polyps are not. This allows CTC to maximize the yield of advanced lesions, most likely to transform to a future cancer but avoid numerous polypectomies, which hold no benefit but increase the risk of complications, such as perforation. As noted, results from large screening programs suggest that such a strategy is effective and safe.^{70,72}

Screening by CTC is appropriate for average-risk individuals (≥50 years old), which represents the largest screening cohort. CTC-based screening is also appropriate for individuals of this age group who have a somewhat elevated risk because of a positive family history. Family history can be defined as a history of cancer in one first-degree relative or two second-degree relatives.⁹¹ Although somewhat controversial, CTC can also be used in the FOBT-positive population. Lesion detection and negative predictive value are high, but questions have been raised about cost-effectiveness because of higher underlying polyp and cancer prevalence in this group.^{3,92,93} Finally, CTC can be substituted when screening colonoscopy is contraindicated in a patient because of comorbidities and sedation issues or if the patient is anticoagulated. Particularly in the setting of warfarin use, CTC is an excellent alternative for screening because the anticoagulation therapy does not have to be interrupted for the procedure. For the small percentage of positive patients who require removal of a large polyp, the anticoagulation can be reversed at a future date for the therapeutic polypectomy. In contrast, screening by CTC is not indicated for individuals at high risk for colorectal carcinoma and polyps for whom the pretest probability for a positive examination is substantially high. These include those with a polyposis syndrome (e.g., familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer syndrome) and inflammatory bowel disease. Patients with these underlying diagnoses are better evaluated by colonoscopy.

DIAGNOSTIC INDICATIONS

CTC can also be used for the evaluation of various diagnostic situations. It represents a less invasive alternative to colonoscopy for the work-up of clinical scenarios such as altered bowel habits, iron deficiency anemia, and nonspecific weight loss, in which one of the concerns is cancer. In terms of cancer detection, a large meta-analysis (49 studies; compiled cohort $N = 11,151$) demonstrated that CTC had a high sensitivity of 96.1%.⁹⁴ Unlike colonoscopy, there is less concern that detection ability with CTC decreases for right-sided cancers. Several population-based studies have indicated decreased detection or protective effects of colonoscopy for proximal colorectal cancers.^{95–97}

In addition to symptomatology, CTC is often used to complete colonic evaluation in the situation of an incomplete colonoscopy.^{93,98} Whereas same-day barium enema following incomplete colonoscopy may have been difficult because of incomplete colonic coating caused by air block, this is not a concern with CTC. Typically, same-day CTC examinations of good diagnostic quality can be performed. The bowel preparation is often supplemented by tagging agents prior to scanning. A typical protocol involves administering 30 mL of diatrizoate after the patient recovers from sedation to minimize aspiration

risk. Scanning occurs 2 hours after contrast administration, allowing for complete colonic fluid tagging in most patients.⁹⁹

STAGING AND SURVEILLANCE

CTC offers a unique opportunity for the initial staging of colorectal cancer and for surveillance following surgical resection. Because of its cross-sectional nature, CTC can assess the colon and extracolonic structures. In both situations, the standard protocol is typically altered; the prone series is undertaken first at low dose, without intravenous (IV) contrast. This is followed by the supine series, in which a standard CT dose and IV contrast are used to allow optimal extracolonic evaluation for involved regional lymph nodes and distant metastases.

In staging, CTC excels in the localization of the primary cancer, particularly in tortuous elongated colons, in which such localization is difficult for colonoscopy, and for the detection of synchronous polyps and cancers.¹⁰⁰⁻¹⁰² Although several studies have reported decent discriminatory ability in tumor wall staging,^{100,102,103} there is general consensus that this evaluation is better undertaken by magnetic resonance imaging or transrectal ultrasound (in the specific case of rectal cancer), in which both modalities can resolve the layers of the bowel wall. In addition to colonic evaluation, CTC can evaluate regional lymph node and distant metastases. With minor image parameter changes, CTC is essentially a contrast CT examination, which currently is the modality of choice for this portion of the staging evaluation.¹⁰⁴

Surveillance after colorectal cancer treatment is an emerging application for CTC.^{105,106} Similar to colonoscopy, CTC allows for intraluminal evaluation for anastomotic recurrences as well as for metachronous polyps and cancers, similar to colonoscopy. Unlike colonoscopy, however, CTC is not limited to the colorectum, where its cross-sectional nature allows for extraluminal evaluation, including local pericolonic recurrences, regional adenopathy, and distant metastases. Kim and associates reported a large Asian, single-institution experience in this area.¹⁰⁶ CTC detected 6 metachronous cancers, including 1 anastomotic recurrence in 548 patients undergoing routine surveillance without clinical suspicion or increasing carcinoembryonic antigen (CEA) levels following prior colorectal cancer resection and treatment. The per-patient sensitivity was 81.8% for advanced adenomas (18 of 22) and 100% for cancer. CTC was also able to detect an extracolonic recurrence in an additional 11 patients, which could not be seen at colonoscopy.

Pertinent Issues

COMPLICATIONS

CTC has a wide safety profile; complications are extremely rare. The lack of complications is a major advantage of CTC over colonoscopy. CTC is a minimally invasive technique that requires the insertion of a soft-tipped, small-caliber catheter a few centimeters into the rectum to insufflate the colon. In contrast, colonoscopy requires the manipulation of a fiberoptic scope across the entire length of the colon. Because of the torque and traction to accomplish placement, sedation and pain control are both needed at colonoscopy. In contrast, no sedation or pain control is needed with CTC, and thus the possible adverse effects from these medications are avoided. The avoidance of sedation can preclude a substantial number

of complications. Such incidents have been reported as occurring in 0.5% of cases at colonoscopy.¹⁰⁷

Most complications with CTC occur with the bowel preparation. Dehydration and fluid shifts are possible, which are decreased with the use of PEG. However, even these complications are not common and are typically minor in severity. A large survey of several U.S. and international institutions has reported that significant complications from bowel preparation are extremely rare, at 0.0009% (2 of 21,923).¹⁰⁸

There was initial concern that the use of CO₂ could cause interference with the body's acid-base balance or create difficulties for patients with chronic obstructive pulmonary disease because of the respiratory excretion pathway. However, this has not been found to be a problem in clinical practice.¹⁰⁸ Additionally, as part of a Scandinavian CRC screening trial (NORCCAP), CO₂ insufflation at screening optical colonoscopy was investigated in a small subset of the screening cohort.¹⁰⁹ The end-tidal CO₂ was not elevated despite the respiratory excretion and no adverse events reported.

Unlike colonoscopy, perforation is not a significant concern. The perforation rate is almost nonexistent with CTC, particularly with the low-pressure nature of automated CO₂ instillation. Perforation rates with CTC are typically more than an order of magnitude less than colonoscopy, 0.009% versus 0.1% for colonoscopy.^{108,110} Two series have reported higher perforation rates of 0.03% to 0.06% with CTC.^{111,112} However, these rates are likely not representative in screening average-risk persons using automated CO₂ insufflation. These series represented high-risk patients with a potentially distal obstructing process (e.g., distal cancers, diverticular disease, inguinal hernia with trapped sigmoid colon) and were conducted with manual, staff-controlled room air insufflation, which can generate very high intraluminal pressures.

It is important to be aware of an imaging finding that can mimic or raise the specter of perforation. Incidental colonic pneumatosis can be infrequently seen following CO₂ administration. The calculated incidence has been reported to be 0.1% of screening patients.¹¹³ As opposed to a true perforation, the patient is typically asymptomatic, without complaint. Although a subset of these patients may undergo some additional monitoring postprocedure, no supportive measures or intervention are required. On 2D review, scattered lucent foci can be seen paralleling the colonic wall (Fig. 53-16). The cause of this phenomenon is not completely certain but may be related to the increased mucosal permeability of CO₂ and appears to occur with increased frequency with the use of CO₂ as opposed to room air. It is postulated that this phenomenon occurs with colonoscopy but would not be seen, because asymptomatic postprocedure patients are typically not imaged with CT.

RADIATION

Radiation exposure with CTC is low, typically less than 50% of that received with standard CT. Previously, the dose was equivalent to a barium enema examination (5-8 mSv) but has decreased over time.¹¹⁴ The average dose is slightly less than 1 year of background radiation or less than 3 mSv.¹¹⁵ Such reductions are possible because of the high contrast between the gas-filled lumen and soft tissue mucosa of the bowel wall. With the newer iterative reconstruction techniques and other methods of dose reduction, doses are rapidly decreasing from this low level. Despite this low-dose nature, radiation exposure

Figure 53-16 Incidental pneumatosis. 2D CTC image shows colonic pneumatosis (arrowhead) in this screening patient. The patient was asymptomatic and remained without complaint with monitoring. No intervention or supportive care needed.

has been raised as an item of concern for CTC, particularly because of its potential application to large portions of the population.^{116,117} This has been fueled by risk prediction models for general CT based on the linear no-threshold theory, which claims a tiny yet finite risk for future cancer induction.¹¹⁸ There is a strong consensus by health radiation physicists that such estimates of quantitative risk should not be done for dose exposures less than 50 mSv because of the range of possible health outcomes, including no or even potentially beneficial health effects at these dose levels.¹¹⁹

It is important to realize that the concerns are theoretical in nature, proposed by one risk model. When looked at directly, in populations with similar dose exposures, there has been no empiric evidence for increased numbers of cancers in these groups. Large studies (up to 174,000 persons) over many years (5 decades in one study) have been conducted in nuclear industry workers, airline pilots, and atomic bomb survivors.¹²⁰⁻¹²² Cancer-related deaths are decreased in nuclear industry personnel compared with the general population. In the atomic bomb survivor data, in which 43% of the entire cohort ($N = 86,572$) received a dose less than 5 mSv, there was no increased incidence of cancer.¹²³ Ironically, it is this dataset from which the linear no-threshold model was developed from the backward extrapolation of the high-dose exposure cohort.

There are additional factors that mitigate risk, even if they are only theoretically true. For example, only the lung bases are included in the imaged field (most theoretically induced cancers are thoracic in origin), and the patient's typical age of 50 years or older further decreases the risk of a future cancer. Furthermore, several studies have modeled the benefit-risk ratio of CTC-based screening versus induced cancers (using the controversial linear risk model). In this worst case theoretical scenario, the benefit highly outweighs the risk. Berrington de González

and co-workers predicted that 24 to 35 colorectal cancers would be prevented for every theoretically induced cancer.¹²⁴

EXTRACOLONIC FINDINGS

The cross-sectional nature of CTC allows for diagnoses outside the colon, despite the lack of IV contrast and low-dose nature of this examination. Because of the potential widespread use of CTC with colorectal screening, this issue has been one of major interest for optimizing the approach to incidental lesions to minimize the cost and complications.^{125,126} There has been increasing recognition that the incidental risks and costs of any imaging examination should be factored into consideration in addition to the primary reason for the examination.¹¹⁷

As with incidental findings in general, there are positive and negative aspects for extracolonic findings. On the one hand, there are many findings that are incompletely evaluated and turn out to be benign after work-up. These incur cost and the potential for complications related to the additional evaluation. On the other hand, a few important unsuspected diagnoses will be made that have substantial impact for the patient. Structured reporting vehicles such as C-RADS and quality metrics help maximize the benefits of extracolonic findings and minimize the disadvantages of this issue.

Although an extensive literature exists specific to extracolonic findings (ECFs) with CTC, there remains debate on the overall benefit-cost balance, which in part is because of heterogeneous results among studies. It is important that population demographics be carefully considered when applying observed ECF rates. The studies reporting very high rates of additional needed work-up typically reflect a study population very disparate from the average-risk screening U.S. population.¹²⁷⁻¹³⁰ When considering low polyp prevalence or screening cohorts that would mirror the U.S. screening population, ECF rates fall into a consistent range. The overall ECF rates are typically 60% to 70% of the population.¹³¹⁻¹³³ However, it is important to recognize that most of these findings do not require additional work-up. For example, when detected, the diagnosis of a renal calculus is made with CTC, and no additional diagnostic work-up is necessary. When ECF rates for findings with potential for additional evaluation are examined, such as the E3-E4 rates in C-RADS, the rates typically range from 7% to 14%.¹³¹⁻¹³⁵ Also, when actual work-up rates are measured, the rates consistently decrease to less than 10%, from 5.5% to 8%.^{30,131-135} In these studies, this has translated into an additional cost of \$24 to \$34 per examination.^{131-133,135} Reasons why recommended work-ups are not undertaken may be that the extracolonic finding is a known finding that has already been evaluated, or because of comorbidities, work-up is not thought to be indicated for the patient.

These costs in regard to the ECF issue are balanced by the detection of clinically significant conditions. Approximately 2% to 3% of the screening cohort will have a clinically important diagnosis made. Two of the more important conditions include extracolonic cancers and abdominal aortic aneurysms (AAAs; Fig. 53-17). One large series of over 10,000 screening patients demonstrated an extracolonic cancer prevalence of 0.35%¹³⁶; AAA prevalence was reported as 0.5%.¹³⁵ Hassan and colleagues proposed that when extracolonic cancers and AAAs are considered, CTC screening strategies are more clinically effective and cost effective colonoscopic screening because of its coincident ability to detect these ECFs.¹³⁷

Figure 53-17 Unsuspected extracolonic finding. **A.** 2D CTC image shows an incidental aortic aneurysm during colorectal cancer screening. The patient was asymptomatic and unaware. **B.** The aneurysm was followed and repaired 5 years later as it began to grow.

Summary

CTC has matured into a clinically effective modality for the evaluation of colorectal polyps and masses. It has been validated by several prospective multicenter trials. CTC is a multicomponent examination requiring optimization of bowel preparation, colonic distention, and imaging acquisition parameters to

provide quality images. There is a learning curve for optimal interpretation. With attention to detail, this examination can detect relevant polyps with great sensitivity and specificity, equivalent to colonoscopy but with less invasiveness and risk for complications. Its main use and greatest impact will likely be in screening for colorectal cancer, but additional indications include diagnostic purposes and cancer staging and surveillance.

Magnetic Resonance Colonography

SOFIA GOURTSOYIANNI | NICKOLAS PAPANIKOLAOU |
NICHOLAS C. GOURTSOYIANNIS

CHAPTER OUTLINE

Prerequisites and Examination Guidelines

Data Analysis

Indications

Accuracy and Clinical Experience

Patient Acceptance

Colonoscopy remains the first and, in most cases, the sole investigation for detection and prevention of colorectal cancer. However, in up to 26% of examinations, the ileocecal valve cannot be reached by the endoscopist because of stenotic lesions or elongated colonic segments.¹⁻³ Although computed tomography colonography (CTC; see Chapter 53) has received great appreciation in the last decade as an alternative colonic cancer screening examination, with a high accuracy for detection of polypoid lesions 1 cm or larger, radiation exposure remains a concern, especially for young patients with colonic pathology who require regular follow-up. In this context, the introduction of magnetic resonance colonography (MRC) holds great promise. The technique is based on the acquisition of MR datasets of the abdomen, with a distinct focus on the large bowel. Because of the noninvasive character and lack of procedural pain and discomfort, patient acceptance is improved compared with colonoscopy. The datasets can be displayed in a multiplanar reformation (MPR) mode on a postprocessing workstation, which enables the analysis of the colonic wall from any desired angle. In addition, virtual endoscopic views can be generated, so lesions may be more accurately defined.⁴ Concurrently with the colonic wall evaluation on MRC images, all abdominal organs within the displayed field of view can be also assessed.⁵

Prerequisites and Examination Guidelines

General contraindications to MR imaging (MRI), including the presence of a pacemaker or metallic, non-MRI-compatible implants, have to be considered prior to MRC referral. In addition, patients with hip prostheses are not considered ideal candidates for MRC because significant artifacts predominantly obscure the anorectal region, downgrading image quality significantly.

A clean colon is required, especially when the clinical question to be answered is in regard to polyp detection. The cleansing method is usually the same, implemented locally for conventional colonoscopy or CTC.

Because most bowel loops are collapsed in their physiologic state, sufficient distention of the bowel is needed to optimize the examination. This allows for reliable differentiation between

the bowel lumen and bowel wall. Most centers use water or barium solutions administered per rectum.⁶⁻⁸ The use of gaseous media has also been proposed, including room air or CO₂.⁹ Prior to rectal filling, spasmolytic agents (e.g., 20 to 40 mg of scopolamine or 1 mg of glucagon) should be administered intravenously. The effect of these agents is threefold:

1. A better degree of bowel distention can be achieved.
2. Bowel spasm is minimized and thereby patient's acceptance is enhanced.
3. Absence of artifacts because bowel motion is reduced.

Patients are positioned in a prone or supine position on the scanner table. If liquid contrast agents are used for luminal distention, 2000 to 2500 mL is administered via a rectal tube, using hydrostatic pressure. The filling procedure should be stopped whenever patients express considerable discomfort. Alternatively, dedicated sequences can be acquired to monitor the filling process, such as nonslice select sequences providing an update image every 2 to 3 seconds.¹⁰ A combination of two large flex surface coils should be used for signal reception to ensure coverage of the entire large bowel. However, use of the body coil may be sufficient, especially for obese patients.

For data acquisition, the use of a 1.5-T scanner equipped with strong gradient systems is preferable. Data collection is mainly performed under breath-hold conditions. Thus, acquisition times of the single sequence should not exceed 20 to 25 seconds. Cardinal sequences used in MRC are the same as the ones used in MRI of the small bowel (MR enterography or enteroclysis; see Chapter 40).¹¹ The acquisition of 2D and/or 3D fast imaging with steady-state precession (FISP) sequences has proven to be quite useful.^{12,13} Image properties are characterized by a mixture of T1-weighted and T2-weighted contrast, leading to a homogenous bright signal of the colonic lumen filled with water and providing good contrast with the colonic wall, which has low signal intensity. Furthermore, 3D T1-weighted MRI scans should be acquired before and at 70 to 80 seconds after intravenous (IV) administration of gadolinium. Data collection is done in coronal and axial planes for all sequences described. Proposed MRC protocol sequence parameters are listed in Table 54-1.

Data Analysis

Whenever a colorectal lesion is found, the analysis has to be repeated using the corresponding, native, T1-weighted dataset. The signal intensities of the lesions should be recorded to calculate the percentage of contrast enhancement. This procedure helps distinguish between residual stool and true colorectal polyps or cancers reliably. Although true colorectal lesions always enhance (Figs. 54-1 and 54-2), residual stool shows the same signal properties on native and contrast-enhanced T1-weighted images. However, scar tissue, (e.g., after appendectomy) may also show a significant percentage of contrast enhancement, thereby mimicking a polyp (Fig. 54-3). In a

TABLE 54-1 Proposed Magnetic Resonance Colonography Sequence Characteristics

Parameter	T1w VIBE	T1w FLASH	True FISP
2D or 3D	3D	2D	3D
Acquisition plane	Coronal	Axial	Coronal
Acquisition time (s)	21	5 × 19*	22
TR (ms)	3.1	158	3.8
TE (ms)	1.1	1.8	1.9
FLIP angle (degrees)	12	70	80
Slice thickness (mm)	1.8	5.0	2.0
No of slices	120	70	96

*Five acquisition blocks of 19 seconds each.
TE, echo time; TR, repetition time.

second step, the FISP sequences should be analyzed. These sequences have been found to be very accurate for the detection of inflammatory bowel lesions.¹²

In contrast to colonoscopy, virtual colonoscopy studies are not limited to endoscopic viewing. In addition, all abdominal organs within the field of view are displayed. This is especially useful in cases of a colorectal carcinoma because the liver and adrenal glands can be evaluated at the same time. Hepatic lesions can be easily detected and characterized because of the availability of dynamic, contrast-enhanced T1-weighted images. Furthermore, relevant lesions in other organs, including the presence of enlarged lymph nodes, may be identified, which helps in accurate colorectal cancer staging.

Figure 54-1 MRC sequences. Comprehensive examination protocol of MR colonography should include T1-weighted images (A), true FISP images (B), and virtual endoscopic reconstructions (C).

Figure 54-2 Colorectal polyp. This colorectal polyp seen in the sigmoid colon (arrow) demonstrated considerable contrast uptake. Analysis of native (A) and postcontrast T1-weighted scans (B) is mandatory. Furthermore, lesions can be displayed in an axial reconstructed plane (C) and on a virtual endoscopic rendering (D).

Figure 54-3 Appendectomy scar artifact. Scar tissue following appendectomy (arrow) may mimic a colonic polyp (C) because of strong contrast uptake comparing the pre- (A) and postcontrast (B) T1-weighted scans.

Indications

MRC has proven to be a suitable tool in patients with incomplete colonoscopy. There are several underlying reasons for incomplete colonoscopy, such as strictures, elongated bowel segments, and insufficient patient acceptance. MRC provides significantly higher completion rates—bowel elongation has no influence on the visualization of colonic segments, and only high-grade stenosis might prohibit the passage of water, which is necessary for the distention of prestenotic segments (Fig. 54-4). In a study investigating 37 patients with MRC after incomplete conventional colonoscopy (CC), only 4% of the bowel segments were not assessable by means of MRC, whereas CC had failed to reach almost 50% of the potentially visible colonic segments.¹⁴ In addition, MRC revealed lesions in the prestenotic segments, which had not been depicted by CC, including two carcinomas and five polyps.

Furthermore, MRC has shown to be suitable for the diagnosis and assessment of colonic inflammatory bowel disease (IBD) (Fig. 54-5).¹⁵⁻¹⁷ In a study of 23 patients with suspected IBD of the large bowel with MRC,¹⁵ bowel wall inflammation was quantified according to four imaging characteristics—bowel wall contrast enhancement, bowel wall thickness, presence of regional lymph nodes, and loss of haustral folds. Consequently, an inflammation score was calculated, which was compared with endoscopic results and clinical data. Over 90% of the colonic segments with IBD changes were correctly identified. For severe inflammation, sensitivity approached 100%. Therefore, MRC may be used for monitoring IBD activity. Furthermore, extramural changes, including abscesses, phlegmon, or fistula formation can be easily depicted, which may not indicated by colonoscopy.¹⁸ MRC has an especially high reported accuracy for the diagnosis of disease activity and severity in the proximal colon.¹⁹

Despite promising results in the assessment of prestenotic bowel segments and IBD, there are no reliable data yet on MR colonography supporting colorectal cancer screening applications. Most colorectal cancers develop over a period of several years from adenomatous polyps. This makes colorectal cancer to a large extent preventable because detection and subsequent

Figure 54-4 Adenocarcinoma of the colon. Severe stenosis caused by colonic adenocarcinoma (arrow) does not permit evaluation of prestenotic bowel segments when using colonoscopy. Such a display is much less difficult with MRC.

removal of polyps eliminate the risk of malignant degeneration. MRC actually provides all important properties of a screening tool. It is not associated with ionizing radiation exposure, and no other side effects are known. However, all experimental studies and data analysis of MRC have been performed so far in preselected patient cohorts. Further studies with larger screening cohorts are needed.

Contrast-enhanced MRC has been reported to have a very high accuracy (84%-100%) in detecting colorectal involvement in women presenting with deep pelvic endometriosis, playing an important role in preoperative mapping.²⁰

Figure 54-5 Crohn's disease with MRC. This patient with Crohn's disease showed increased contrast enhancement of the transverse colon (arrows) on the T1-weighted image (A) and bowel wall thickening on the true FISP image (B).

Accuracy and Clinical Experience

The accuracy of MRC for the detection of colorectal masses and IBD has been assessed in a number of studies. The largest study to date included 100 patients evaluated with MRC¹⁰; conventional colonoscopy was performed following the MRC examination on the same day and served as the standard of reference. MR data acquisition included pre- and postgadolinium T1-weighted images, which were compared with endoscopic and histologic results. Colonoscopy revealed a total of 107 colorectal masses. MRC was able to identify all masses larger than 10 mm and 84.2% of polyps between 6 and 9 mm in diameter. Overall specificity of MRC amounted to 96.0%, and only a very small number of false-positive results were found. MRC showed a high accuracy for the detection of adenomas and carcinomas larger than 6 mm. These results were confirmed by a study that included patients at high risk.⁵ Over 100 subjects with suspected colorectal disease underwent MRI, with colonoscopy serving as the standard of reference. None of the lesions smaller than 5 mm was identified by MRC, probably because of lower spatial resolution. However, the sensitivity for the detection of lesions between 5 and 10 mm amounted to 89%. Also, all colorectal masses larger than 10 mm, including nine carcinomas, were correctly diagnosed with MRC.

Diagnostic accuracy and image quality appear to be related to the type of MR sequences used. Thus, the application of fast imaging with true FISP or contrast-enhanced, T1-weighted images have been found to result in different image quality and accuracy.¹² Lauenstein et al,¹² in a study comparing MRC and colonoscopy, used true FISP and postcontrast T1-weighted fast low-angle shot (FLASH) images. T1-weighted imaging provided all-over sensitivity values of almost 80% for the detection of colorectal pathologies. Furthermore, there were no false-positive results because residual stool could be easily distinguished from colorectal masses because of the lack of contrast enhancement. True FISP sequences, however, had a lower sensitivity, approximately 70%. False-positive results were identified in 14% of the examinations, most probably related to the

difficulty of distinguishing between residual stool and colorectal masses. Interestingly, image quality of FISP turned out to be significantly better than that of T1-weighted imaging; because of lower motion sensitivity, fewer artifacts caused by respiratory or patient motion were noticed (Fig. 54-6). These results indicate that the main diagnostic evaluation, at present, should be based on the T1-weighted data, although true FISP sequences may provide useful information, especially in uncooperative patients.

One major criticism still relates to the very limited accuracy of MRC to detect colorectal polyps smaller than 5 mm. The clinical significance of these lesions remains controversial, because most of them are not prone to malignant degeneration.²¹ Small polyps will probably become detectable by MRC in the future. Technical improvements, such as parallel acquisition techniques (PATs), have certainly helped increase spatial resolution.²² However, flat adenomas are likely to remain elusive.

A qualitative assessment of diffusion weighted imaging (DWI)—obtained images (highest b value of 1000 s/mm²) was carried out for the detection of clinically significant colorectal polyps (≥ 6 mm) in 26 patients who underwent colonoscopy. On a per-lesion basis, a sensitivity of 80% and a positive predictive value (PPV) of 73% have been reported. As such, DWI cannot be recommended in a clinical setting when CC is to be performed in patients with positive findings on DWI.²³ DWI-MRC, however, has been reported to be a reliable tool for detecting colonic inflammation in ulcerative colitis, even without bowel preparation.²⁴

Patient Acceptance

Bowel cleansing has been a mandatory prerequisite for MRC because fecal material may mimic the appearance of colonic masses. However, bowel preparation is considered unpleasant by most patients and may lead to symptoms ranging from feeling unwell to an inability to sleep.^{25,26} Patient's acceptance for MRC could be significantly increased if bowel preparation

Figure 54-6 Motion artifacts on MRC. True FISP images (**A**) are less prone to motion artifacts than T1-weighted gradient echo images (**B**) and may therefore provide helpful information, especially for patients who are not able to hold their breath.

Figure 54-7 Fecal material visibility with tagging. **A.** Note that on the true FISP image the fecal material presents with moderate signal intensity (arrows). **B.** Fecal material (arrows) may be rendered almost invisible on T1-weighted images by means of fecal tagging.

could be eliminated. Different strategies have been proposed and tested to accomplish this. One successful approach is fecal tagging, which leads to a modification of signal characteristics of fecal material. For this, specific oral contrast compounds have to be ingested over 48 hours prior to the MR examination. The signal properties of stool are thereby adapted to the signal characteristics of the rectal enema. Thus, fecal material becomes almost invisible (Fig. 54-7).

Barium sulfate solutions have been used for fecal tagging. Administered orally, with 200 mL given with each of four main meals prior to the MR examination, barium decreases the signal intensity of fecal material on T1-weighted gradient recalled

echo (GRE) images.^{8,26,27} Thus, feces are rendered almost indistinguishable from the water enema administered (Fig. 54-8). Fecal tagging with barium has been successfully tested in volunteer and patient studies.^{8,28} However, ingestion of barium was considered as unpleasant as bowel cleansing.

Patient experiences of MRC and conventional colonoscopy have been compared in small cohorts of those having undergone both examinations, and it has been found that the experience is rather complex and strongly influenced by the clinical indications. IBD patients have reported more physical discomfort during conventional colonoscopy but were more satisfied with received feedback.²⁹

Figure 54-8 Large polyp on MRC. This large polyp (arrow) is depicted in two consecutive turbo FLASH coronal views. Homogeneous suppression of the intraluminal signal can be achieved through optimization of the inversion time, whereas the absence of motion-related artifacts can be explained in the sequential data acquisition of the turbo FLASH sequence.

Colonic diverticula are acquired herniations of the mucosa and of portions¹ of the submucosa through the muscularis propria. Diverticular disease of the colon represents a continuum from an initial, prediverticular phase of marked muscular thickening of the colon wall (myochosis) to frank outpouchings (diverticulosis) and finally to diverticular perforation (diverticulitis). Disease progression from the initial phase to the advanced phases does not necessarily occur.¹ In this chapter, we discuss the natural history of this disease and focus on radiologic diagnosis and intervention.

Diverticulosis

EPIDEMIOLOGY

Diverticular disease is the most common colonic disease in the Western world. Interestingly, this disease was a pathologic curiosity before the 20th century. Its modern development is attributable to the introduction of the roller milling process in 1880, which removes most of the fiber from flour. This process results in a low-residue diet producing low-volume,

tenacious stools that require a high degree of propulsive effort for expulsion.^{2,3}

In Western countries, colonic diverticula occur in 5% of the population by 40 years of age, in 33% to 50% of the population after 50 years of age, and in more than 50% of the population after 80 years of age.^{2,3} Among patients of routine risk, diverticulosis is found in 71% of patients on colonoscopy age 80 years or older.⁴ These findings contrast sharply to the prevalence rate of less than 0.2% in underdeveloped areas of Asia and Africa.⁵ In individuals from low-prevalence areas who migrate to Western communities, the frequency of diverticula increases within 10 years.^{1,6}

The sigmoid colon is involved in up to 95% of patients.⁷ Japan is an interesting exception to other developed countries in that patients with right-sided diverticulosis predominate at younger ages, subsequently becoming more bilateral over time.⁸ Of all patients who harbor diverticula, and 20% of those whose diverticula are clinically recognized, 4% to 5% will develop some complication, 1% to 2% will require hospitalization, and 0.5% will need surgical intervention, radiologic intervention, or both.^{4,5} In 2011, diverticulosis and diverticulitis were listed as the principal discharge diagnosis in 329,165 cases, accumulating over \$11 billion in hospital charges in the United States. In-hospital deaths were listed as 1,858 cases (0.56%).^{9,10}

CAUSATIVE FACTORS

The two fundamental factors contributing to the development of sigmoid diverticula are a pressure gradient between the lumen and serosa and areas of relative weakness in the bowel wall. The first factor can best be appreciated by considering the tendency of the colon to function not as a tube but as small compartments created by the haustra (segmentation). The sigmoid is the narrowest portion of the colon and generates the highest intrasegmental pressures, an example of the law of Laplace. In addition, stool is most dehydrated in the sigmoid colon, further increasing segmentation and motor activity.^{6,10}

The colon wall is weakest where the intramural vasa recta penetrate to the submucosal layers. These points are on either side of the taenia mesocolica and on the mesenteric side of the taenia libera and taenia omentalis (Fig. 55-1).^{2,3} Diverticula do not usually occur on the haustral row between the taenia omentalis and taenia libera.^{2,3}

PATHOPHYSIOLOGY

Most colonic diverticula are false diverticula, or pseudodiverticula, because they contain mucosa and submucosa but not the muscularis propria (Fig. 55-2). They are usually 0.5 to 1.0 cm in size and penetrate the clefts between bundles of circular muscle fibers at points where nutrient arteries pass through the

Figure 55-1 Site of origin of colonic diverticula. **A.** Diverticula develop on either side of the mesenteric taenia and on the mesenteric side of the antimesenteric taenia, taenia omentalis (TO), and taenia libera (TL). These are the sites (arrows) at which the vasa recta perforate the muscularis propria and penetrate the submucosa (inset). **B.** The antimesenteric TO-TL haustral row does not give rise to diverticula. TM, mesenteric taenia. (**A** from Dietzen CD, Pemberton JH: Diverticulitis. In Yamada T [ed]: *Textbook of Gastroenterology*. Philadelphia, JB Lippincott, 1991, pp 1734–1748; **B** from Meyers MA, Volberg F, Katzen B, et al: *Haustral anatomy and pathology: A new look: II. Roentgen interpretation of pathologic alterations*. *Radiology* 108:505–512, 1973.)

submucosa. The proximity of the diverticula to the arteries is considered key in the development of hemorrhage.^{2,3,11}

In the uninfamed state, diverticula are elastic and compressible but have a tendency to empty poorly and, as a result, to fill with inspissated stool. This tendency may account for the increased number of lymphoid follicles found in the lining mucosa.^{2,3} Most patients with sigmoid diverticula have myochosis, a disorder in which there is thickening of the circular muscle layer, shortening of the taeniae, and narrowing of the lumen. The circular muscle is often corrugated, and its appearance has been likened to that of a concertina.^{2,3}

Diverticula of the rectum are rare, likely because the taeniae become fused anteriorly and posteriorly at this level, forming a completely encircling, supporting coat. Rectal diverticula are true diverticula and are usually lateral.^{12–14}

CLINICAL FINDINGS

In most patients, diverticulosis is an incidental finding. Patients may complain of symptoms of irritable bowel syndrome, such as chronic or intermittent postprandial lower abdominal pain, which is relieved by defecation.

RADIOLOGIC FINDINGS

Radiographic Studies

More than 50% of patients with significant diverticular disease demonstrate a distinctive bubbly appearance of the sigmoid colon on routine abdominal radiographs. When pelvic phleboliths are present, there is a statistical correlation between their number and size and the degree of diverticular disease. It is postulated that both these common disorders are caused by the long-term effects of a low-fiber diet and straining while defecating.^{15,16}

Barium Studies

Diverticulosis is detected more often by double-contrast studies than by single-contrast studies because of the greater colonic distention and improved visualization of intramural diverticula (Fig. 55-3). When viewed en face, these immature diverticula may simulate aphthae. Their true nature is established when they are viewed in profile, when they are conical or triangular and 1 to 2 mm high.^{17–20}

The mature diverticulum has several characteristic appearances (Fig. 55-4) that depend on the angle with which it is viewed and degree of barium filling. In profile, the diverticulum appears as a flasklike protrusion measuring several millimeters to several centimeters in length, joined to the wall by a fairly long, large neck. En face, it may appear as a ring shadow or a well-margined barium collection or may resemble a bowler hat (Fig. 55-5). The size and form of diverticula vary from one moment to the next, depending on the degree of colonic distention. The alignment of diverticula along the taeniae is usually apparent.^{20–25}

Diagnostic difficulties may arise if the diverticulum inverts into the lumen, and a number of diverticular polypectomies have been described in the endoscopic literature. Also, if feces obstruct the diverticulum, the diverticular orifice may bulge into the lumen, resulting in a ring shadow or filling defect. In profile, only the neck of the diverticulum may be visible. If the obstruction is incomplete, a fine linear strand of barium may penetrate the diverticulum, simulating a spur. Because this strand of barium appears outside the lumen, its presence usually allows the correct diagnosis to be made. For this reason, careful attention to the appearance of polyps and diverticula from film to film is necessary.^{20–26}

A diverticulum with a large neck may resemble a sessile polyp, one with a narrow neck may resemble a pedunculated polyp, and an obstructed diverticulum may resemble a polyp or adherent fecal material. In addition, both polyps and diverticula can produce the so-called bowler hat sign. If the bowler hat points toward the center of the long axis of the colon, it represents a polyp. If it points away from the center of the long axis of the bowel, it represents a diverticulum. If the bowler hat is located in the midline of the bowel, or is directly parallel to the long axis of the bowel, it cannot be confidently classified as representing a polyp or diverticulum.^{20–25}

Figure 55-2 Diverticula: pathologic findings. **A.** Diverticula (black arrow) arise adjacent to the taenia coli, where there is weakness in the bowel wall from penetration of the vasa rectae. The appendices epiploicae (blue arrows) lie adjacent to these diverticula. It is not surprising that epiploic appendagitis and diverticulitis can have similar clinical features. **B.** Histologic image shows that diverticula consist of herniated mucosal and submucosal layers and lack the muscularis propria. **C.** Colonoscopic view of multiple diverticula in the sigmoid colon. The orifice of the diverticula is evident (arrows). **D.** Gross specimen of colon. Diverticula readily fill with stool but empty it poorly.

Figure 55-3 Colonic diverticulosis: double-contrast barium enema features. Multiple barium-filled outpouchings are identified along the lateral aspect of the proximal descending colon.

Figure 55-4 Variable appearance of diverticula on double-contrast barium enema. The appearance of diverticula depends on the angle from which they are viewed and how much barium or air they contain. (From Bartram CI, Kumar P: *Clinical Radiology in Gastroenterology*. Oxford, England, Blackwell Scientific, 1981, p 130.)

Figure 55-5 Distinguishing features of polyps and diverticula. **A.** Polyps. **B.** Diverticula. (From Bartrum CI, Kumar P: *Clinical Radiology in Gastroenterology*. Oxford, England, Blackwell Scientific, 1981, p 131.)

Figure 55-6 Colonic myochosis. **A.** The thickened circular muscle (arrow) and shortened taeniae lead to the appearance of a concertina. **B.** Longitudinal section of the same sigmoid colon segment shows narrowing of the lumen and prominent haustra (arrows), which are staggered. (From Weissman A, Clot M, Brellet J: *Double Contrast Examination of the Colon*. Berlin, Springer-Verlag, 1985, p 150.)

Caliber and haustral abnormalities (Fig. 55-6) usually accompany and often antedate the appearance of diverticula, particularly in the sigmoid colon. Haustral clefts are usually symmetric and face one another in the sigmoid; however, in diverticular or prediverticular disease, they indent alternately from one border to another, creating a staggered effect. The circular muscle is hypertonic and thickened, and the taeniae contract. Diverticula originate at the top of the haustra. With progressive disease, the circular muscle continues to undergo hypertrophy and a concertina or zigzag appearance develops. This appearance is caused by the alternated, highly compact, deep, and uniform haustra that separate and segment the haustral cul-de-sacs.¹⁷⁻²⁵

Figure 55-7 Diverticulosis: CT findings. CT scan at the level of the sigmoid colon shows multiple air- and contrast-filled diverticula (arrows).

Computed Tomography

Computed tomography (CT; Fig. 55-7) reveals mural thickening of the colon (>4 mm) in myochosis and in most cases of diverticulosis. The diverticula appear as outpouchings that contain air, stool, and/or contrast agent.

Diverticulitis

EPIDEMIOLOGY

Diverticulitis is the most common complication of diverticulosis. Traditionally, this has been estimated to occur in 10% to 25% of patients with diverticulosis.^{27,28} The true incidence is likely less, with one study of Veterans Administration patients establishing an incidence closer to 4%.²⁹

Simple, or uncomplicated diverticulitis, will occur in 75% of initial presentations. Complicated diverticulitis, defined as the presence of an abscess, fistula, obstruction, or perforation, is seen in the remaining 25%.³⁰

PATHOPHYSIOLOGY

The stagnation of nonsterile, inspissated fecal material within the diverticulum can cause inflammatory erosion of the mucosal lining in early, subclinical stages of diverticulitis. Subsequently, the wall of the diverticulum is eroded. This perforation is the essential feature of diverticulitis (Fig. 55-8A).^{2,3}

This sequence of events can involve an intramural diverticulum, leading to the formation of an intramural abscess. Usually, it occurs extramurally within the pericolic fat, leading to fibrinous exudate, abscess formation, local adhesions, or peritonitis. During surgery and pathologic examination, many juxtacolic abscesses are small and difficult to find in the mass of indurated fat and fibrous tissue. It is important to emphasize that the inflammation begins at the apex of the diverticulum and may spread rapidly into the soft pericolic and mesocolic fat. The inflammatory changes in diverticulitis are therefore mainly pericolic, adjacent but outside the bowel wall.^{2,3}

The colonic mucosa is not affected in diverticulitis, except in the region of the erosion. Most inflammatory complications of clinical significance are secondary to the rupture of a diverticulum, and they occur in a pericolic location in almost all cases. Consequently, these pathologic changes may be better described as peridiverticulitis or pericolitis. True diverticulitis, with inflammation limited to the diverticular lining, was present in 10% of pathologic specimens, and muscular hypertrophy, with distortion alone and without inflammation, accounted for the remaining 25% of cases.^{2,3}

The consequences of diverticular rupture depend on the host response and virulence of the bacterial contamination.^{2,3} Most patients develop sealed-off abscesses or contained sinus tracts and fistulas. Free perforations are uncommon but can lead to

localized pelvic or generalized peritonitis. Fistulas involve adjacent structures, such as the small bowel, urinary bladder, vagina, and anterior abdominal wall. Occasionally, several adjacent diverticula communicate with each other along the outer aspect of the deep muscular layers, forming an intramural fistulous tract. In other cases, fistulas extend deeply into the fatty tissue at the site of the attachment of the sigmoid mesocolon.^{2,3}

CLINICAL FINDINGS

The classic clinical features of sigmoid diverticulitis are left lower quadrant pain, tenderness, fever, and leukocytosis. Because of this clinical constellation, sigmoid diverticulitis has been termed *left-sided appendicitis*. Diverticulitis occurring in other colonic locations is more difficult to diagnose clinically. In one review, the following clinical features were noted: pain in the left iliac fossa in 85% of patients; palpable mass, tenderness, and muscle guarding in 48%; fever in 30%; vomiting in less than 50%; and partial obstruction in 20%. Mild bleeding occurred in 25% of patients, and about 33% of patients had a history of recurrent episodes of similar attacks. Surgical evaluation of this group of 258 patients showed a 20% incidence of pericolic abscess, 8% incidence of fistulas, and 18% incidence of peritonitis. The initial clinical diagnosis was sigmoid carcinoma in 32% of patients, but carcinoma was found in only 2% of patients. The occurrence of malignancy was entirely coincidental, but it highlights the clinical difficulties of diagnosing and evaluating patients with suspected acute diverticulitis. These difficulties are further documented by large surgical series of patients with a clinical diagnosis of acute diverticulitis, in whom 25% to 33% of the resected surgical specimens showed no active inflammation, abscess, or fistulas.^{1-3,26-28,31}

Severe diverticulitis can occur in certain groups of patients and produce only minimal or unremarkable clinical symptoms, such as debilitated older patients, patients who have renal failure, are undergoing dialysis, or have had renal transplantation, and patients receiving corticosteroids. Disease in these

Figure 55-8 Diverticulitis. A. Pathologic specimen showing perforation of a diverticulum into the pericolic fat, a finding diagnostic of diverticulitis. **B.** Double-contrast barium enema shows mass effect on the medial aspect of the junction of the descending colon and sigmoid (arrows). There is distortion of the lumen, but the extent of extracolonic disease cannot be assessed.

patients may progress to free perforation, and the diagnosis is often made only when free intra-abdominal air is detected on abdominal films.^{2,3,30}

Patients younger than 40 years have historically been reported to have more severe forms of diverticulitis, ultimately requiring surgery.³² Some reports have suggested that younger patients follow the same course as older patients, and the decision for surgery should be made similarly.^{33,34}

The clinical management of patients with acute diverticulitis depends on the severity, type, and extent of the pericolic inflammatory changes. Mild forms of disease are managed medically with antibiotic therapy. A large recent Swedish study, however, concluded that mild acute uncomplicated diverticulitis may be successfully treated with anti-inflammatory agents, with no additional benefit from antibiotics.³⁵ In more severe forms, surgical resection may be indicated, either at the time of the diagnosis or after a cooling-off interval of antibiotic therapy and percutaneous abscess drainage. One study demonstrated emergent surgical intervention in 12% of patients admitted for diverticulitis.³⁶ This has decreased over time, partly because of increased use of image-guided percutaneous drainages.^{37,38} Emergent surgery is reserved for Hinchey 3 or 4 acute diverticulitis.

Close clinical and radiologic evaluation are crucial for the triage of patients to conservative, radiologic, or surgical management. The radiologic investigation of these patients has two objectives—to confirm the clinical suspicion of diverticulitis (and rule out other colonic or pelvic disease) and evaluate and stage the severity of the inflammatory disease. Sigmoidoscopy is usually contraindicated and serves no useful purpose except in patients who have more chronic forms of disease and present with bleeding, or in patients in whom polyps or sigmoid carcinoma is suspected.

RADIOLOGIC FINDINGS

Radiographic Studies

Abdominal radiographs taken with the patient supine and upright are usually diagnostic only in the most severe forms of diverticulitis, in which the patient presents with free intraperitoneal air or sealed-off perforations and pelvic extraluminal air. The detection of an ill-defined, left-sided pelvic mass, localized ileus, and fluid in the pelvis suggests the diagnosis in the appropriate clinical setting. In most patients with acute diverticulitis, however, abdominal plain films are unremarkable and do not contribute to the diagnosis.

Contrast Enema Examination

Contrast enema (CE) examination had traditionally been the primary method of examining patients with suspected diverticulitis, but now has been replaced by CT as the initial diagnostic test. It superbly depicts diverticula, colonic mucosa and lumen, spasm, muscle hypertrophy, and sacculations. These findings, however, are indicative of diverticular disease but not diagnostic of acute diverticulitis. Because this procedure primarily evaluates the colonic lumen and mucosal surface, the pericolic inflammatory process present in most patients with diverticulitis can only be inferred (Fig. 55-8B).¹⁷⁻¹⁹

A specific diagnosis of perforated diverticulitis can be made only when there is extravasation of contrast material from a diverticulum into a walled-off abscess, sinus tract, or fistula or free extravasation of contrast material into the peritoneal cavity.

These extraluminal collections of contrast medium vary in size, are usually located adjacent to the colon, compress and displace the colonic wall, and are detected in less than 50% of cases of diverticular perforation. Narrowing of the sigmoid lumen, extrinsic compression, and spasm are present in more than 80% of patients, but these findings are less specific. Similarly, an altered mucosal pattern is present in 68% of patients but is not a reliable indicator of acute inflammation. Lack of mobility with fixation of the sigmoid colon and narrowing, pointing, and distortion of individual diverticula are indirect signs consistent with acute or chronic diverticulitis.¹⁷⁻¹⁹

A contour defect that is smooth, well defined, and associated with adjacent sigmoid diverticula represents an intramural inflammatory mass. The contents of the intramural mass, whether pus, organized abscess, or merely mural fibrosis, are more difficult to characterize. Tracts filled with contrast material passing from ruptured diverticula into the pericolic tissues are common (Fig. 55-9). They may be single or multiple, end blindly (sinuses), or connect with an adjacent hollow viscus or abdominal wall (fistulas). The most common fistulas are colovesical and coloenteric. Colocutaneous fistulas are less frequent and are clinically associated with subcutaneous abscess, emphysema, or fasciitis. Fistulas to the vagina, ureter, appendix, hip, perineum, and soft tissues of the thigh have also been reported. With CE, the fistulous tract between the colon and urinary bladder is visualized in only 20% of patients who have colovesical fistulas.¹⁷⁻¹⁹

Longitudinal intramural fistulous tracts represent ruptured diverticula that communicate with each other. Although this sign has also been reported in carcinoma of the colon and Crohn's disease, longitudinal intramural fistulous tracts most often are caused by diverticulitis unless there is a previous history or radiographic evidence of Crohn's disease in the remainder of the colon or terminal ileum.

Figure 55-9 Diverticulitis with pericolic abscess: barium enema features. Spot image from a barium enema shows filling of an abscess (A) and a sinus tract (arrows) along the inferior aspect of the sigmoid colon.

Ultrasonography

Although multidetector CT (MDCT) is the primary cross-sectional imaging study for patients with suspected diverticulitis, ultrasonography (US) may be the first study ordered for nondescript abdominal pain and for pregnant patients suspected of having diverticulitis. The advantages of ultrasound are the lack of ionizing radiation and relative lower cost. Ultrasound is practically and technically more difficult in obese and severely ill patients, and is operator-dependent. US should be performed with a graded compression technique. One meta-analysis has demonstrated no significant difference in the accuracy of graded compression US and CT in diagnosing diverticulitis, with CT more likely to find alternative causes of abdominal pain.³⁹ Additionally, CT has been found to be more sensitive in the evaluation of complicated diverticular disease, better demonstrating abscess and free air.⁴⁰

The segmental concentric thickening of the gut wall commonly found in patients with diverticular disease manifests as a hypoechoic segment that reflects the predominant thickening of the muscular layer (Fig. 55-10). Sonographic findings of

Figure 55-10 Diverticulitis: sonographic features. There is mural thickening of the sigmoid colon associated with a gas-containing intramural abscess (arrow) that casts an acoustic shadow.

Figure 55-11 Diverticulitis: MRI features. **A.** Coronal T2-weighted MRI scan of the descending colon demonstrates mural thickening, increased signal from the colonic mucosa, and abnormal signal in the pericolic fat (arrow). **B.** Axial T2-weighted image without fat suppression demonstrates abnormal T2 signal within the pericolic fat and mural thickening. A small amount of free fluid is also present.

diverticulitis include segmental wall thickening more than 4 mm, echogenic adjacent pericolic fat that is noncompressible, and inflamed diverticula. Local pain on compression is also a typical finding. Inflamed diverticula are brightly echogenic reflectors with acoustic shadowing or a ring-down artifact in or beyond the thickened gut wall. There may be adjacent fluid. Intramural sinus tracts appear as high-amplitude linear echoes that often have a ring-down artifact within the colon wall. A fecalith will be echogenic, with posterior acoustic shadowing. Abscesses appear as loculated, thick-walled fluid collections that may contain gas.⁴¹⁻⁴⁴

Magnetic Resonance Imaging

Mural thickening of the colon (Fig. 55-11) and diverticular abscesses are well visualized on magnetic resonance imaging (MRI), particularly on gadolinium-enhanced, fat-suppressed, T1-weighted spoiled gradient-echo images and T2-weighted, single-shot echo-train spin-echo images. Inflammatory change within the adjacent fat can be seen on non-fat-suppressed and fat-suppressed images. Sinus tracts, fistulas, and the walls of abscesses enhance and are well depicted in a background of suppressed fat on gadolinium-enhanced, fat-suppressed, spoiled gradient-echo images.⁴⁵

The major advantage of MRI is the lack of ionizing radiation. The disadvantages of MRI are longer scan times, greater susceptibility to motion artifact from the adjacent bowel, and relative higher cost. Given the efficiency and effectiveness of CT in the assessment of diverticulitis and its complications, MRI has little role in the primary evaluation of routine patients with known or suspected diverticulitis. MRI could be considered in special situations, such as pregnant patients, because of the lack of ionizing radiation.

Computed Tomography

MDCT has dramatically improved the diagnosis and management of patients with diverticulitis. MDCT is ideally suited for evaluating the intramural component of the inflammatory process and its intraperitoneal or retroperitoneal extension. CT is particularly useful in the evaluation of patients with sepsis who present with left lower quadrant pain, fever, leukocytosis, and a tender, palpable pelvic mass. CT has a reported accuracy, specificity, and sensitivity of up to 99%.^{32,46} Current guidelines recommend a CT with intravenous (IV) contrast as the initial test for patients with suspected diverticulitis.⁴⁷ Oral contrast is

not practically necessary, but may help in the evaluation of fistulas and with bowel distention.

CT findings in acute diverticulitis are listed in Table 55-1. On non-contrast-enhanced scans, the offending diverticulum can often be identified. It is hyperdense and is the nidus of the surrounding inflammation (Fig. 55-12). Diverticula are identified on CT at the site of the perforation or at a site adjacent to it in more than 80% of cases of acute diverticulitis. They appear as small outpouchings filled with air, barium, and/or fecal material projecting through the colonic wall. Symmetric thickening of the colonic wall in excess of 4 mm is seen in about 70% of cases. The thickened wall has a homogeneous density, and its diameter usually measures less than 1 cm in the distended colon. When there is significant muscular hypertrophy, the wall of the colon can be up to 2 or 3 cm thick. In diverticulitis, significant hypertrophy of muscle primarily occurs in the sigmoid

segment, which can mimic carcinoma of the colon. Accurate assessment of colon wall thickness is possible only with proper lumen distention.^{26,48}

The hallmark of acute diverticulitis on CT is the presence of inflammatory changes in the pericolic fat. This sign is seen in 98% of patients. The degree of inflammatory reaction varies, depending on the size of perforation, bacterial contamination, and host response. In mild cases, there is only a slight increase in the attenuation of fat adjacent to the involved colon, with engorgement of the vasa recta (Fig. 55-13). Fine linear strands, small fluid collections, and several bubbles of extraluminal air may be present (Fig. 55-14). In more severe cases, pericolic heterogeneous soft tissue densities representing phlegmons (Fig. 55-15) and/or intramural or extraintestinal loculated fluid collections representing abscess can occur. In sigmoid diverticulitis, fluid in the combined interfascial plane in the pelvis is a common finding.^{26,48}

On CT, abscesses appear filled with fluid and may contain bubbles of air or air-fluid levels (Fig. 55-16). These collections can form at a distance from the involved segment of colon. They may form at the flank, groin, thigh, psoas muscle, subphrenic space, or liver. Most abscesses are contained within the sigmoid mesocolon or are sealed off by the sigmoid colon and adjacent small bowel loops.^{26,48}

A sealed-off perforation with the resulting juxtacolic inflammatory reaction causes thickening of the sigmoid mesocolon or the adjacent parietal peritoneum. Although this is not a specific finding, it is often seen in diverticulitis and helps in identifying the site and focal nature of the inflammatory process. Small, 1- to 2-cm intramural fluid collections representing intramural abscesses can be detected. Intramural or pericolic fistulas can be recognized as linear, fluid-filled tracts within or parallel to the thickened colonic wall. Blind sinus tracts and fistulas manifest as linear or tubular branching structures in the pericolic tissues. They can communicate with adjacent organs or terminate in an abscess cavity.

TABLE 55-1 Multidetector Computed Tomography Findings in Diverticulitis

Finding	No. of Cases (%)
Mural thickening of the colon	96
Fat stranding	95
Adjacent diverticula	91
Fascial thickening	50
Visualization of inflamed diverticulum	43
Pericolic gas bubbles	30
Arrowhead sign	16
Abscess	4
Phlegmon	4
Intramural gas	2
Sinus tracts	2

Modified from Kircher MF, Rhea JT, Kihiczak D, et al: Frequency, sensitivity and specificity of individual signs of diverticulitis on thin-section helical CT with colonic contrast material: Experience with 312 cases. *AJR* 178:1313–1318, 2002.

Figure 55-12 Diverticulitis: MDCT findings on non-contrast-enhanced scans. Sagittal (A) and axial (B) images show the hyperdense offending diverticulum (curved arrow) at the center of the pericolic inflammation. Note the thickening of the anterior (small straight arrow) and lateroconal (large straight arrow) interfascial planes. C. Coronal reformatted image in a different patient demonstrates a hyperdense diverticulum with surrounding inflammatory change (arrow).

Figure 55-13 MDCT of diverticulitis: early changes. **A.** Axial CT scan of the sigmoid colon demonstrates mural thickening with haziness of the sigmoid mesocolon (arrows) associated with engorged vasa recta. **B.** Axial postcontrast CT scan shows mural thickening and pericolic inflammatory change in the transverse colon, with hyperdense diverticulum (arrow).

Figure 55-14 MDCT of diverticulitis: intramural abscess. Axial CT of the sigmoid colon shows mural thickening, pericolic inflammatory changes, and fascial thickening with the presence of an intramural abscess (arrow).

Figure 55-16 MDCT of diverticulitis: abscess. **A.** Axial image in one patient demonstrates a large abscess with an air-fluid level (A) identified in the pelvis. **B.** Coronal image in a different patient demonstrates similar findings.

SURGICAL AND COMPUTED TOMOGRAPHY STAGING

Diverticulitis can be staged surgically (Fig. 55-17) and by CT. Familiarity with the following staging system (modified Hinchey classification) helps in directing therapy and assessing prognosis (Table 55-2):

- **Stage 0 diverticulitis** is the most common form, in which the inflammation is contained within the serosa. This mural inflammation usually responds well to antibiotics. On CT, it appears primarily as mural thickening, with little inflammatory change in the surrounding fat.⁴⁹
- **Stage Ia diverticulitis** denotes confined pericolic inflammation or phlegmon. CT findings demonstrate phlegmonous changes only. These patients do well with antibiotic therapy and seldom progress to stage II or III disease.^{49,50}
- **Stage Ib diverticulitis** denotes diverticulitis with a confined pericolic abscess.⁴⁹ Abscesses smaller than 3 cm can be treated with antibiotics alone. Percutaneous CT guided drainage is usually performed in patients with amenable abscesses larger than 4 cm.^{50,51}
- **Stage II diverticulitis** signifies that the pericolic abscess has broken through the sigmoid mesocolon and has become walled off by the small bowel, greater omentum, fallopian tubes, or other pelvic structures. This stage is associated with abscesses 4 to 15 cm in diameter that are well suited to percutaneous drainage (Fig. 55-18).⁵¹⁻⁵³ Percutaneous drainage is used as a bridge from the acute setting to subsequent elective colon resection. In select patients with comorbidities, however, the need for surgery can be established after successful percutaneous drainage.^{28,49,54,55}
- **Stage III diverticulitis** signifies pelvic abscess that has spread beyond the confines of the pelvis to involve other portions of the peritoneal cavity. CT findings demonstrate changes of diverticulitis with free air and/or free

fluid.⁵⁰ This represents a generalized purulent peritonitis. Fortunately, this form of diverticulitis is relatively infrequent because the body's defenses usually contain the perforation.⁴⁹ Traditionally, this is treated with emergent sigmoid resection in a one- or two-stage procedure. In select patients, the use of laparoscopic peritoneal lavage for patients with stable Hinchey stage 3 can be used as a definitive treatment or as a bridge to subsequent colonic resection.⁵⁶

- **Stage IV diverticulitis** is defined as fecal spread into the peritoneal cavity. A wide-mouthed perforation is usually present. The CT appearance may be similar to that of stage III with free air and/or free fluid, but these patients have acute peritonitis with life-threatening sepsis, so they usually undergo immediate exploratory laparotomy.⁴⁹

Together with the clinical evaluation, CT is used not only to confirm the clinical suspicion but also as a reliable guide to patient management. Patients with mild diverticulitis (pericolic inflammation, small abscess [<3 cm]) are treated conservatively with antibiotic therapy and bowel rest. Patients with larger abscesses (>4 cm) are percutaneously drained. Emergency surgery is reserved for cases of free perforation with peritonitis.²⁸ Elective colonic resection after an episode of complicated diverticulitis or multiple episodes of diverticulitis should be decided on an individual basis.²⁸

DIFFERENTIATION OF DIVERTICULITIS FROM CARCINOMA

Diverticulitis can mimic colon cancer clinically on barium enema examination, US, MRI, and MDCT. On CE studies, the detection of partial colonic obstruction with sigmoid

TABLE 55-2 Staging and Classification of Diverticulitis		
Stage	Modified Hinchey Classification*	CT Staging†
0	Mild clinical diverticulitis	Diverticula, with or without wall thickening
Ia	or	Colonic wall thickening with pericolic soft tissue changes
Ib	Pericolic-mesocolic abscess	Ia changes with pericolic-mesocolic abscess
II	Pelvic, distant intra-abdominal, retroperitoneal abscess	Ia changes with distant abscess
III	Generalized purulent peritonitis	Free air with localized or generalized ascites
IV	Generalized feculent peritonitis	Same findings as III

narrowing, a gradual zone of transition, preservation of the mucosal folds, and associated diverticula indicate diverticulitis (Fig. 55-19). Abrupt transition at the site of obstruction, a rigid, narrowed lumen, destruction of mucosa, and a so-called apple core configuration suggest carcinoma of the colon. CE is valuable in differentiating diverticulitis from carcinoma of the sigmoid colon in most cases. The presence of sigmoid diverticula, however, is not helpful in the differential diagnosis because 28% of sigmoid cancers involve coincidental diverticula.⁵⁷ When the retrograde flow of contrast medium is impeded and the obstructed sigmoid lumen cannot be well visualized, the differentiation of an inflammatory lesion from a malignant lesion cannot be made.

CT features that suggest diverticulitis include identification of the offending hyperdense diverticulum, inflammation of the adjacent fat with engorgement of the vasa recta, fluid at the root of the mesentery (in the combined interfascial plane), fluid and inflammatory changes out of proportion to the mural thickening, abscess formation, extraluminal fluid, and gas. CT features favoring carcinoma include prominent adjacent lymph nodes; symmetric or asymmetric mural thickening with shouldered, nontapered margins; and presence of a luminal mass. There is considerable overlap of CT findings. If there is a long segment of colonic thickening with pericolic inflammatory change and no pericolic lymph nodes, diverticulitis is the most likely diagnosis. When pericolic lymph nodes are seen adjacent to a segment of colonic thickening, colon cancer is the most likely diagnosis.⁵⁸⁻⁶⁰

In approximately 10% of patients, diverticulitis cannot be differentiated from colon carcinoma on the basis of CT scans. Most patients with diverticulitis exhibit only mild circumferential wall thickening, in the range of 4 to 5 mm. Excessive thickening of the colonic wall, concentrically or focally, suggests colonic neoplasm. Although most colon cancers are more than 2 cm thick, neoplastic lesions less than 1 cm in diameter may be seen. These facts account for a significant overlap in colonic wall thickness in diverticulitis and carcinoma, particularly with lesions that are between 1 and 3 cm in thickness. An abrupt zone of transition with overhanging edges and a narrow, rigid lumen indicates carcinoma; a tethered or saw-toothed luminal configuration suggests diverticular disease. Associated inflammatory mesenteric changes favor diverticulitis, whereas regional lymphadenopathy favors carcinoma of the colon.^{58,60,61}

CT perfusion may help in the differentiation between colon cancer and diverticulitis. One small study showed that blood volume, blood flow, and mean transit time and sensitivities of 80%, 80%, and 85%, respectively, could help discriminate between the two. Permeability showed a specificity of 90%.⁶⁰ The incorporation of CT perfusion into routine clinical practice, however, remains a challenge.

The differential diagnosis of cancer versus diverticulitis is extremely difficult in patients presenting with perforated colon carcinoma associated with pericolic inflammation or abscess. An abruptly altered lumen caliber with an asymmetric and lobulated soft tissue mass is diagnostic of perforated sigmoid carcinoma.

After a CT diagnosis of sigmoid diverticulitis, current guidelines recommend follow-up CE or endoscopic visualization.²⁸ This may not be necessary in all cases, particularly acute uncomplicated diverticulitis.⁶²⁻⁶⁴ Lymph nodes, abscess, obstruction, wall thickness more than 6 mm, or other complicating factors of diverticulitis may represent more refined CT criteria requiring near-term (usually 6 weeks) follow-up with CE or colonoscopy.⁶³

CHRONIC DIVERTICULITIS

Chronic diverticulitis, a variant of acute diverticulitis with longer duration of symptoms, is characterized by more obstructive symptoms. CE enema findings demonstrate long segment narrowing with spiculated contour and tapered margins, occasionally with an associated obstruction. CT demonstrates findings similar to those of acute diverticulitis (Fig. 55-20).⁶⁵ One study of CT colonographies demonstrated that the most important discriminator was the presence of diverticula, with the affected segment favoring chronic diverticulitis. This study also reinforced the findings favoring diverticulitis versus carcinoma and vice versa (see earlier).⁶⁶

DIFFERENTIAL DIAGNOSIS

Other conditions such as nonspecific or infectious colitis, ischemic colitis, and Crohn's disease are part of the differential diagnosis of diverticulitis. A long segment of colonic involvement, lack of diverticula, absence of a focal inflammatory pericolic process, or pericolic air collection helps in the CT differential diagnosis. Foreign bodies that escape CT detection

Figure 55-19 Colon cancer versus diverticulitis: imaging considerations. **A.** Barium enema examination demonstrates an indeterminate stricture in the sigmoid colon. Multiple diverticula are present but there is an abrupt, overhanging edge (arrows) along the proximal margin of this lesion. This patient had diverticulitis and carcinoma of the sigmoid colon. **B.** Focal, symmetric mural thickening of the sigmoid colon is present. There are inflammatory changes in the fat of the sigmoid mesocolon. Several diverticula are evident just distal to the region of thickening. This patient had diverticulitis. **C.** There is a mass identified within the lumen of the sigmoid colon, with only minimal haziness of the adjacent fat. This patient had carcinoma of the sigmoid colon. **D.** Line drawings showing features that suggest diverticulitis (inflammation, pericolic edema, fluid in the root of the mesentery—combined interfascial plane, extraluminal fluid and air) versus carcinoma (eccentric thickening, luminal mass). **E.** Axial CT demonstrates an intraluminal mass with diverticula seen along the margins of the mass, but not in the segment with the mass. There are equivocal surrounding inflammatory changes. This patient had carcinoma of the sigmoid colon. (**D** from Chintapalli KN, Chopra S, Ghiatas AA, et al: Diverticulitis versus colon cancer: Differentiation with helical CT findings. *Radiology* 210:429–435, 1999.)

and perforate the colon can mimic the CT findings of acute diverticulitis.

Epiploic Appendagitis

Primary epiploic appendagitis, a relatively common condition resulting from an acute inflammation of appendices epiploicae often associated with torsion and infarction, can be confused as diverticulitis. This is frequently seen in patients younger than those with diverticulitis. CT will show the characteristic appearance of a small, round, or oval fat-containing mass with associated inflammatory reaction adjacent to the colon (Fig. 55-21). Frequently, a central dot representing a thrombosed vessel is seen.⁶⁷ The lack of adjacent colonic wall thickening can differentiate this from acute diverticulitis.⁶⁸ Complications of diverticulitis including abscess, extraluminal gas, and inflamed diverticula are not seen with primary epiploic appendagitis. The

process is self-containing, with clinical resolution within a few days. Follow-up CT examination may show total resolution or shrinkage, with eventual calcification of the inflamed and infarcted epiploic appendage.

Cecal Diverticulitis

Cecal diverticulitis or right-sided colonic diverticulitis is a relatively rare pathologic entity in which patients present with protean clinical manifestations that are often clinically misdiagnosed as appendicitis. Cecal diverticula are classified as true (congenital) or false (acquired). The congenital variety is usually larger and solitary and is characterized by the presence of a well-developed muscle coat. Most cecal diverticula are acquired and are similar to diverticula present in the remainder of the colon. They are usually multiple, involve the cecum and ascending colon, are formed by herniated mucosa and serosa, and lack a muscular coat. Traditionally, barium examination represented the primary means of preoperative diagnosis, but CT is now the mainstay in the evaluation of cecal diverticulitis and its differential diagnosis, including appendicitis and carcinoma. The characteristic findings of the barium enema examination include a filling defect with an irregular contour, cecal spasm, fixation and spiculation of the cecal wall, visualization of diverticula, and a normal appearance of the appendix.⁶⁹

The CT findings consist of focal pericolic inflammatory changes, slight thickening of the wall of the colon, demonstration of diverticula and, occasionally, an intramural or pericolic fluid collection representing an abscess (Fig. 55-22). When a normal appendix is seen and the focal pericecal inflammatory process is above the cecal caput, a reliable CT diagnosis can be made. If the appendix is not seen, findings similar to those of appendicitis or perforated cecal carcinoma make the CT diagnosis uncertain. Recent experience indicates that the diagnosis of right-sided colonic diverticulitis can be suggested or established by MDCT.⁷⁰

Figure 55-20 Chronic diverticulitis. Axial CT image shows pericolic inflammatory changes, with extensive long segment wall thickening.

Figure 55-21 Epiploic appendagitis: MDCT features. **A, B.** These two different patients have a fat-density mass (arrow) surrounded by increased attenuation adjacent to the sigmoid colon. This fatty mass is the epiploic appendage that has undergone torsion, ischemia, and/or inflammation.

Figure 55-22 Right-sided diverticulitis: imaging considerations. **A.** Coronal reformatted image shows the hyperdense offending diverticulum (arrows) associated with considerable inflammatory change in the adjacent fat. **B.** Axial scan of different patient shows contrast filling a normal appendix (curved arrow) and the offending diverticulum (straight arrow). **C.** Postcontrast coronal reformatted CT image demonstrates focal pericolic inflammatory changes, with wall thickening and suggestion of the inflamed diverticulum (arrow). **D.** Note the contrast-filled posterior to the cecum on the axial image (arrow).

Figure 55-23 Fistulas from diverticulitis. **A.** Fistulogram showing injection of a skin wound and direct communication to the sigmoid colon. **B.** A fistula (arrow) from the sigmoid colon to the ileum is identified on this barium enema examination.

COMPLICATIONS

Perforation of one or several diverticula produces a localized inflammatory reaction and may lead to the development of a sinus tract, intramural tract, or variable-sized intramural or pericolic abscess. Other more unusual complications can sometimes occur.

Fistulas and Sinus Tracts

Fistulas (Fig. 55-23), which are communications between two epithelium-lined surfaces—bowel to another hollow organ, or bowel to skin—can develop and be difficult to detect. Fistulas have been reported in up to 20% of surgical cases of diverticulitis.⁷¹ Diverticulum-related fistulas are usually to the bladder,

but fistulization to the vagina (usually in patients who are status posthysterectomy), uterus, adnexae, small and large bowel, and others is also encountered.⁷²

CT is extremely useful in the evaluation of patients with suspected colovesical fistulas. CT has a high sensitivity and provides useful information about the surrounding anatomic structures.⁷³ It should be used as the first imaging modality in patients suspected of having a colovesical fistula.

In patients presenting with pneumaturia, the pericolic inflammatory mass involving the bladder wall and the presence of intraluminal vesical air confirms the diagnosis. Sigmoid-vesical fistulas rarely occur in the acute setting during the initial attack of diverticulitis and the development of the pelvic abscess. Colovesical fistulas are mostly seen as late sequelae after one or several episodes of diverticulitis, when the acute inflammatory reaction has already subsided. Thickening of the bladder wall, thickening of the bowel wall adjacent to the bladder, gas in the bladder, insinuating mass, and direct adherence of the colon to the bladder are all findings that may indicate a fistula. A discretely opacified fistula and oral contrast medium within the bladder are more direct signs (Fig. 55-24).^{73,74}

Free Intraperitoneal Perforation

As noted, severe forms of diverticulitis, and particularly free perforations, occur rarely and are seen mainly in debilitated

older individuals and patients on corticosteroid therapy. Free diverticular perforation results in extravasation of air and fluid into the pelvis and peritoneal cavity with the development of peritonitis. On CT (Fig. 55-25), bubbles of air are seen floating in the pelvic fluid close to the sigmoid colon, as well as free in the greater peritoneal cavity. Occasionally, a sigmoid diverticulum can perforate into the leaves of the mesosigmoid, and air can dissect into the retroperitoneum of the left pelvis and left upper abdomen. This presentation, when associated with bubbles of air adjacent to the sigmoid colon, is diagnostic of perforated diverticulitis.

Bowel Obstruction

Diverticulitis is the third most common cause of a large bowel obstruction, seen in approximately 10% of cases, behind colorectal cancer and volvulus.⁷⁵ This can be seen in the acute and chronic setting. The colon can become obstructed because of luminal narrowing caused by inflammation or compression by an abscess (Fig. 55-26). Multiple attacks can lead to progressive fibrosis and stricture of the colonic wall. Obstruction generally is self-limited and responds to conservative therapy. If persistent, obstruction of the colon can be treated by a variety of endoscopic and surgical techniques.

Diverticulitis is a rare cause of small bowel obstruction. The small bowel loops become trapped in the perisigmoid

Figure 55-24 Colovesical fistula caused by diverticulitis. **A, B.** Indirect evidence of a fistula with inflammatory changes of the sigmoid colon and adjacent eccentric bladder wall thickening (arrow).⁷³ **C, D.** Direct evidence of a colovesical fistula with an air-filled tract between the sigmoid colon and bladder (arrow), with gas seen in the bladder.

Figure 55-25 Free intraperitoneal perforation.

A. Lateral scout image demonstrates free intraperitoneal gas (arrow). **B.** Axial image of the pelvis demonstrates the gas-containing region of perforation (arrows). **C.** Several bubbles of gas are evident anterior to the liver (arrows). **D.** Noncontrast CT in a different patient demonstrates free air adjacent to the liver (arrows). **E.** Diverticulitis is noted, with extensive diverticulosis in the sigmoid colon.

inflammatory process, and the associated mesenteric changes can be detected by MDCT (Fig. 55-27).⁷⁶

Pylephlebitis and Liver Abscess

The acute infection, originating from a left- or right-sided diverticulitis, can spread into the liver via mesenteric venous drainage and portal vein. The septic thrombosis that develops, called pylephlebitis or septic thrombosis of the portal vein, represents a serious complication seen in severely ill patients with septic manifestations and no localizing signs. CT can reveal air or thrombus in the draining mesenteric veins and

thrombus in the mesenteric and portal veins (Fig. 55-28). Sometimes, during the initial presentation or on follow-up examination, a pyogenic liver abscess may develop (Fig. 55-29). The primary colonic inflammatory process can be detected by CT as an intramural inflammatory mass or pericolic abscess. This complication carries an overall mortality of 32%. Patients should be diagnosed early and be closely monitored and adequately treated with a combination of antibiotic therapy, percutaneous abscess drainage, and surgical intervention, when necessary. Anticoagulant therapy may also be used.^{77,78}

A. There is a gas-containing abscess (arrows) in the sigmoid mesocolon. **B.** A multiloculated abscess is identified in the left lobe of the liver (arrows).

Diverticular Hemorrhage

Diverticular disease is the most common cause of lower gastrointestinal bleeding in the United States, accounting for 17% to 40% of cases.⁷⁹ In one study, diverticular disease accounted for 42% of patients hospitalized for lower GI bleeding.⁸⁰ It usually is difficult to confirm the exact cause of bleeding, however. Although diverticula predominate in the sigmoid and descending colon, angiographic confirmation of diverticular bleeding has been documented throughout the colon, with one study noting a 60% incidence in the right colon.⁸¹ One study of 180 patients in Asia demonstrated that right-sided disease was more likely to present with massive hemorrhage and require surgery, whereas left-sided disease was more likely to present with diverticulitis.⁸² The use of nonsteroidal anti-inflammatory drugs (NSAIDs) or aspirin, hypertension, and/or anticoagulation are risk factors.⁸³

PATHOPHYSIOLOGY

The source is typically a single diverticulum, which in 80% of cases is not inflamed. There is minute rupture of one of the vasa recta asymmetrically placed in the wall adjacent to the lumen of the diverticulum (Figs. 55-30 and 55-31). Eccentric intimal thickening, duplication of the internal elastic lamina, and thinning of the media are changes that are all found with the involved artery. An eccentric focus of media thickening, intramural thickening and duplication, and fragmentation of the internal elastic lamina in the wall of the involved artery at the point of its disruption are seen. Some traumatic factor within the lumen of the diverticulum induces this eccentric intimal thickening, which eventually weakens and ruptures the vasa recta. The wider domed necks of right-sided colonic diverticula may expose these vessels to injury over a greater length, explaining the strikingly high incidence of right-sided hemorrhage.⁸⁴

CLINICAL FINDINGS

Most patients with massive diverticular hemorrhage are older adults, with severe coexistent cardiovascular and pulmonary disease, and they present with a sudden onset of mild abdominal cramps and the urge to defecate. Soon after, a large volume of bright red blood, clots, or both, or dark red, maroon or, least commonly, black stool is passed rectally. Bleeding ceases

Figure 55-30 Diverticulum formation and vascular relationships.
A. The vas rectum penetrates the colon wall from the serosa to the submucosa through an obliquely oriented connective tissue septum in the circular muscle (CM). This penetration occurs near the mesenteric side of the taenia (T). **B.** The diverticulum develops through and widens this connective tissue cleft. The mucosal protrusion begins to elevate the artery. **C.** As the diverticulum extends transmurally, the vas rectum is placed over its dome, penetrating to the submucosa on the antimesenteric border of its neck and orifice. (From Meyers MA, Volberg F, Katzen B, et al: *Angioarchitecture of colonic diverticula: Significance in bleeding diverticulosis*. Radiology 108:249–261, 1973.)

spontaneously in approximately 75% of patients, but the bleeding may be continuous or intermittent.⁸⁵ The rebleeding rate in patients without definitive therapy was 9% at 1, 10% at 2, 19% at 3, and 25% at 4 years.⁸⁰ The differential diagnosis, radiology, and treatment of diverticular hemorrhage are discussed elsewhere in this text (see Chapter 125).

Figure 55-31 Pathogenesis of colonic diverticular hemorrhage. Progressive eccentric changes weaken the wall of the vas rectum, which eventually ruptures into the lumen of the diverticulum. (From Meyers MA, Alonso DR, Gray GF, et al: *Pathogenesis of bleeding colonic diverticulosis*. *Gastroenterology* 71:577–583, 1976.)

Figure 55-32 Giant sigmoid colon diverticulum. A giant sigmoid colon diverticulum (GSD) is demonstrated in two different patients on a barium enema study.

Giant Sigmoid Diverticulum

CAUSATIVE FACTORS

A giant sigmoid diverticulum is a rare complication of diverticulitis. It is believed to result from subserosal perforation and inflammation of a diverticulum, with subsequent air trapping and eventual formation of a large cyst, which is caused by elevated intraluminal pressure of the colon working in tandem with a ball valve mechanism. In time, inflammatory and granulation tissue replaces the mucosal lining of the cyst wall. The trapped air in the cyst increases during defecation and is vented irregularly.⁸⁶⁻⁸⁸

PATHOPHYSIOLOGY AND CLINICAL FINDINGS

Most patients are elderly and have a history of chronic vague abdominal discomfort or acute symptoms suggesting diverticulitis. A palpable mass is detected in 71% of cases, and anatomic communication between the cyst and the lumen is present in 82%. The cysts range in size between 6 and 27 cm, with a mean diameter of 13 cm. The cyst may be hyperresonant on percussion.⁸⁶⁻⁸⁹

RADIOLOGIC FINDINGS

The barium enema (Fig. 55-31) and plain radiograph findings in giant sigmoid diverticulum are striking. Plain radiographs demonstrate a large gas-filled structure in the lower to middle pelvis that can have an air-fluid level. The gas collections may change in size on interval studies.⁸⁶⁻⁸⁹

Barium enters these collections on contrast agent studies in two thirds of patients, and diverticula are seen elsewhere in the colon in 82% of patients. The differential diagnosis of these large collections includes volvulus, giant Meckel's or other small bowel diverticulum, tubo-ovarian abscess, cystitis, emphysematous cholecystitis, infected pancreatic pseudocyst, and vesicoenteric fistula.⁸⁶⁻⁸⁹ On CT, a giant sigmoid diverticulum appears as a gas- or contrast-filled structure communicating with the colon (Fig 55-32).

THERAPY

Giant colonic diverticula have been reported to perforate, cause volvulus and infarction and small bowel obstruction, and may contain carcinoma. The accepted therapy for giant colonic diverticula is surgical excision.⁸⁶⁻⁸⁹
